four times daily) for at least 14 days; patients with more chronic disease can be switched to fluconazole (400 to 800 mg daily) for a longer duration of therapy, typically for several weeks.

Treatment of *Candida* eye infections varies with the extent of ocular involvement. Lesions discovered early at the stage of choroidal or retinal involvement can be treated effectively with intravenous amphotericin B (3 to 5 mg/kg), an echinocandin (e.g., caspofungin 50 mg daily, micafungin 100 mg daily, or anidulafungin 100 mg daily), fluconazole (400 mg daily), or voriconazole (200 mg twice daily) for at least 2 weeks after the first negative blood culture. Many experts prefer to use an agent, such as voriconazole or fluconazole, that achieves higher concentrations in the eye. Lesions extending into the vitreous require more aggressive therapy. The best results have been obtained with pars plana vitrectomy, injection of amphotericin B or voriconazole into the vitreous, and a systemic antifungal agent such as fluconazole (400 mg daily) or voriconazole (200 mg twice daily) for several weeks. Management must be individualized and performed in concert with an ophthalmologist experienced in the treatment of this infection. Treatment of endophthalmitis associated with an intraocular lens implant requires removal of the implant, vitrectomy and local amphotericin B injections, as well as therapy with fluconazole or voriconazole.

PREVENTION

For patients at the highest risk for invasive candidiasis and other fungal infections, prophylactic antifungal agents can prevent infection. The populations for whom prophylaxis is recommended include stem cell transplant recipients (Chapter 163), patients with acute leukemia who are undergoing induction chemotherapy (Chapter 168), high-risk liver transplant recipients (Chapter 140), and pancreas and small bowel transplant recipients. In these groups, a variety of different agents are effective. In the ICU population, prophylaxis with fluconazole (400 mg daily) can be effective, but it is recommended only in units that have a high rate of invasive candidiasis, and only in patients at the highest risk for infection. For example, using caspofungin (50 mg daily) as antifungal prophylaxis in adults who were in the ICU for at least 3 days, were ventilated, received antibiotics, had a central line, and had at least one additional risk factor was safe and reduced the incidence of invasive candidiasis in one randomized trial, but the benefit was not statistically significant.[A7] Restricting the use of prophylaxis to individuals at higher risk for candidiasis is essential to prevent the widespread use of azoles, with subsequent selection of resistant species. An experimental vaccine has shown promise in reducing recurrent symptomatic vulvovaginal candidiasis.[A8]

PROGNOSIS

The prognosis for patients with mucocutaneous infections is excellent. The prognosis for focal invasive infections depends on the organ involved and the patient's immune status. For example, whereas pyelonephritis may respond well to antifungal therapy, endocarditis and meningitis are more difficult to treat and have poor outcomes.

For invasive candidiasis, overall mortality is about 30 to 40%.[20] Significant predictors of mortality include increasing age, use of immunosuppressive therapy, and infection with *C. tropicalis*. Improved survival and clinical success are associated with early treatment with an effective antifungal agent, the use of an echinocandin, and the removal of central venous catheters. In candidemic patients who have septic shock, mortality rates as high as 98% are seen in patients in whom antifungal therapy and effective source control (i.e., draining abscesses and removing central venous catheters) is delayed beyond 24 hours after the onset of shock.

311 ASPERGILLOSIS

THOMAS J. WALSH AND THOMAS F. PATTERSON

DEFINITION

Aspergillosis is a disease caused by one or more of the species of the genus *Aspergillus*. Sporelike structures called *conidia* are aerosolized from the mold form of the organism growing in the environment. When conidia reach tissue, they germinate to form invasive filaments called *hyphae*.

The Pathogens

The most common species infecting humans are *Aspergillus fumigatus, Aspergillus flavus, Aspergillus terreus*, and *Aspergillus niger. Aspergillus* species are usually identified in culture by characteristic microscopic features of hyphae and the structures producing conidia. When some species are not readily identifiable, they may be reported by the clinical laboratory as "*Aspergillus* species" or "*Aspergillus* sp." *A. fumigatus* may be reported as "*A. fumigatus* species complex." *A. terreus* is resistant to amphotericin B. Aspergilli within tissue appear as dichotomously branched (Y-shaped) septate hyphae. *Scedosporium* and *Fusarium* species also may produce septate hyphae in tissue. The presence of septa and dichotomous branching differentiates *Aspergillus* species from the Mucorales, which are the causative organisms of mucormycosis (Chapter 312).

EPIDEMIOLOGY

Aspergillus species are ubiquitous organisms in the external environment, including soil, decaying matter, and air, in temperatures as high as 40 to 50° C. Aspergilli are easily isolated from houses, particularly from basements, crawl spaces, bedding, humidifiers, ventilation ducts, potted plants, dust, condiments (e.g., pepper), and marijuana samples. Aspergilli cause abortion in cattle and are important pathogens of marine organisms, insects, and domesticated and wild birds. Aflatoxin, which is one of the most potent carcinogens known, is produced by strains of *A. flavus* at ambient temperature on stored grain, spices, and nuts. Foodborne ingestion of preformed aflatoxin may cause hepatic necrosis or hepatocellular carcinoma (Chapter 181) in animals and humans.

Aspergillus species may be acquired from airborne conidia in inpatient and outpatient health care settings. Nosocomial aspergillosis is associated with building renovation, new construction, unfiltered air, contaminated ventilation systems, and fireproofing materials. Hospital water, which may become aerosolized during activities such as showering, also can be a potential source of aspergilli. As human pathogens, *Aspergillus* species may cause acute invasive disease, chronic infection, or allergic symptoms[1] (Table 311-1).

Acute invasive aspergillosis develops in immunocompromised patient populations, particularly patients with severe neutropenia (Chapter 153), hematologic malignancies,[2] hematopoietic stem cell transplantation (Chapter 163), severe aplastic anemia (Chapter 151), primary immunodeficiencies (Chapter 231), and solid organ transplantation, especially of heart, lung, and liver. Genetic deficiency of the soluble pattern-recognition receptor called PTX3 (long pentraxin 3) caused by homozygous haplotype (h2/h2) in the *PTX3* gene of donor cells leads to impaired neutrophilic antifungal capacity and an increased risk for invasive aspergillosis in recipients of stem cell transplants. Persistent neutropenia, corticosteroids, other immunosuppressive agents, graft-versus-host disease (GVHD), and cytomegalovirus disease are the most frequently observed clinical risk factors. Patients who have influenza

ABSTRACT

Aspergillosis propagates by airborne conidia and invades tissue by hyphae. *Aspergillus fumigatus* is the most common species. *Aspergillus* species are found ubiquitously in nature and in buildings. *Aspergillus* species cause acute invasive diseases of the lungs and sinuses from which dissemination to other tissues may occur in immunocompromised patients. They also cause chronic pulmonary infections and allergic sinopulmonary diseases. Acute invasive pulmonary aspergillosis is diagnosed in immunocompromised patients by a combination of symptoms, diagnostic imaging features (nodules, halo signs, cavities), and microbiologic features, including bronchoalveolar lavage. Disseminated infection is best diagnosed by direct biopsy or needle aspirate. Chronic forms of aspergillosis include aspergilloma, chronic necrotizing aspergillosis, and chronic cavitary aspergillosis. Allergic bronchopulmonary aspergillosis may develop in patients with asthma and in those with cystic fibrosis. Treatment of invasive aspergillosis relies on a triad of antifungal therapy, reversal of immunosuppression, and, where appropriate, surgical resection of infected tissue. Voriconazole or isavuconazole is recommended as the preferred agents, but posaconazole and liposomal amphotericin B are considered acceptable alternatives of comparable efficacy.

(Chapter 332) and immunosuppressed patients with coronavirus disease 2019 (COVID-19; Chapter 336) also are at risk for pulmonary aspergillosis.[3,4]

Invasive aspergillosis complicates the care of up to 13% of immunocompromised patients. Invasive aspergillosis is associated with increased hospital mortality and 30-day readmission rates, as well as excess duration of hospitalization and costs.

PATHOBIOLOGY

Conidia of *Aspergillus* spp. are the key infectious propagules that are acquired by humans from the inanimate environment via organisms that grow in decaying organic matter. These asexual, sporelike structures are 3-5 μ in diameter and have an outer surface covered by rodlets composed of hydrophobin proteins that confer hydrophobicity and adherence to mammalian cell surfaces. The hydrophobins and dihydroxynaphthalene melanins of conidia protect the fungus against host defenses. Inhaled conidia are mechanically cleared by the mucociliary escalator of the pseudostratified columnar respiratory epithelium. Conidia that reach the alveolar space adhere to pulmonary alveolar macrophages via lectin-like attachment sites, including dectin-1, DC-SIGN, and pentraxin 3. When (1→3)-β-D-glucans of swollen conidia are recognized by dectin-1, macrophages are activated to release cytokines and chemokines. Conidia are normally engulfed within phagosomes and destroyed via nonoxidative phagolysosomal mechanisms. Conidia that are not destroyed may germinate to form hyphae, which are then damaged by neutrophils.

These innate host defenses are abrogated in immunocompromised patients. Corticosteroids suppress phagocytosis and nonoxidative killing by macrophages. The recruitment of neutrophils is dependent on the release of chemokines by the lung epithelial cells and CARD 9 signaling. Defects in CARD9 signaling can lead to increased host susceptibility to *Aspergillus*. Defects in the genes encoding NADPH oxidase lead to chronic granulomatous disease, which strongly predisposes to invasive aspergillosis. Neutropenia and neutrophil dysfunction allow hyphae to invade the respiratory epithelium and vascular endothelium, thereby leading to thrombosis, infarction, and hemorrhage. Among the putative virulence factors of *A. fumigatus*, serine proteases, elastases, phospholipases, and gliotoxin further contribute to tissue injury, invasion, and dissemination.

This capacity to invade blood vessel walls (angioinvasion) results in hemorrhagic infarction. These processes lead to formation of a necrotic center surrounded by a ring of hemorrhage and edema, which correlates with a "halo sign" surrounding the nodular density. Galactomannan, which is a heteropolysaccharide of the *Aspergillus* cell wall, is a useful biomarker that is released into the circulation and alveolar spaces during invasive pulmonary aspergillosis. (1→3)-β-D-glucan is another *Aspergillus* cell wall polysaccharide that is detected in serum during invasive disease.

An aspergilloma consists of a fungal ball composed of matted hyphae and debris in a preformed cavity from previous pulmonary tuberculosis, histoplasmosis, or fibrocystic sarcoidosis. Chronic necrotizing pulmonary aspergillosis characteristically causes a slowly progressive inflammatory destruction of lung tissue superimposed on chronic lung disease. Chronic cavitary pulmonary aspergillosis is defined as the presence of multiple *Aspergillus*-related cavities, which may or may not contain an aspergilloma. Patients with chronic cavitary pulmonary aspergillosis may have genetically mediated deficits in innate host defenses.

Allergic bronchopulmonary aspergillosis results in a hypersensitivity response that develops in the chronic settings of asthma (Chapter 75) and cystic fibrosis (Chapter 77) with a type I hypersensitivity response that results in elevated IgE to *Aspergillus* antigens, mast cell degranulation, and bronchoconstriction. Type III hypersensitivity reactions in allergic bronchopulmonary aspergillosis result in elevated interleukin (IL)-4 and IL-5, the latter contributing to eosinophilia.

CLINICAL MANIFESTATIONS

Acute Invasive Aspergillosis

Invasive Pulmonary Aspergillosis

The classic clinical manifestations of invasive pulmonary aspergillosis in immunocompromised hosts are fever and focal pulmonary infiltrates, nodules, or wedge-shaped densities resembling infarcts.[5] Cough, pleuritic pain, and hemoptysis also may be present. Focal pulmonary infiltrates may progress to a cavity on recovery from neutropenia. Pulmonary infiltrates may also present as bronchopneumonia in an immunosuppressed patient. Concomitant pleural effusion may develop and represent *Aspergillus* empyema. Tracheobronchial aspergillosis in immunocompromised patients presents as ulcerative, pseudomembranous, or plaquelike large airway disease that may presage pulmonary parenchymal invasion. This invasive form has been seen in mechanically ventilated patients,[6,7] including patients with COVID-19 (Chapter 336).

Acute Sinusitis

Acute *Aspergillus* sinusitis may occur concomitantly or independently of invasive pulmonary aspergillosis. Although symptoms may include fever, localized pressure, and pain, they may be absent in severely immunocompromised patients. Eschar on the nasal septum and turbinates may be observed by speculum examination or endoscopy. Acute *Aspergillus* sinusitis of the ethmoid and sphenoid sinuses may progress to cavernous sinus thrombosis with symptoms referable to cranial nerves III, IV, $V_{1,2}$, and VI. *A. flavus* has a high propensity for causing acute sinus infection.

Extrapulmonary Aspergillosis

The tissue targets of extrapulmonary and disseminated aspergillosis most commonly include the CNS,[8] where abscesses and infarcts are characteristic. Patients with CNS aspergillosis present with focal paresis, cranial nerve deficits, and seizures. The glucose level in cerebrospinal fluid (CSF) is usually normal, and cultures of CSF are negative. Other extrapulmonary manifestations include endophthalmitis, myocardial infarction, gastrointestinal disease, renal infarction, cutaneous lesions, and Budd-Chiari syndrome. Esophageal ulcers and mesenteric thrombosis may produce gastrointestinal bleeding. Renal infection may present as flank pain and hematuria.

Aspergillus endocarditis usually begins as an isolated infection in intravenous drug users or after cardiac valvular surgery. *Aspergillus* endocarditis most commonly presents as major arterial emboli to brain, lung, kidney, and bone. Blood cultures, which are seldom positive, may be delayed in growth by as much as 14 to 21 days. *Aspergillus* pericarditis may arise from contiguous pulmonary lesions or through transmural infection from endocardial infection.

Locally invasive aspergillosis usually develops in immunocompromised patients as cutaneous ulcers, focal rhinitis, osteomyelitis, and septic arthritis. Cutaneous ulcers have been associated with use of contaminated adhesive tape and arm boards. Keratitis, endophthalmitis, and infection of burn wounds may develop from traumatic inoculation in otherwise immunocompetent patients.

Chronic Pulmonary Aspergillosis

Aspergilloma

An aspergilloma appears on chest radiograph as a fungus ball in a cavity (Fig. 311-1).[9] Symptomatic patients present with cough, hemoptysis, dyspnea, weight loss, fatigue, chest pain, or fever. Sputum culture is typically positive for *Aspergillus* species, particularly *A. niger*. Pleural aspergillosis may complicate surgical resection of aspergilloma or develop spontaneously as a bronchopleural fistula or concomitantly with tuberculosis.

As a stage in the repair process of infarcted lung tissue in neutropenic patients, one or more apparent "aspergillomas" may develop in consolidated lesions during recovery from neutropenia. These apparent aspergillomas do not develop in preexisting cavities and create an "air-crescent sign," or Monod sign, during their formation.

Chronic Necrotizing Pulmonary Aspergillosis

Chronic necrotizing pulmonary aspergillosis and chronic cavitary pulmonary aspergillosis occur in patients with underlying chronic lung disease and chronic immunosuppression. In chronic necrotizing disease, the clinical manifestations of worsening pulmonary function, cough, and dyspnea may be indistinguishable from concomitant primary chronic respiratory disease.

Chronic cavitary disease occurs with symptoms of cough, hemoptysis, and dyspnea. The progressive cavities of chronic cavitary pulmonary aspergillosis tend to coalesce with the loss of functional lung tissue.

Aspergillus otomycosis is a chronic infection that usually involves the external auditory canal with symptoms of pain, pruritus, hypoacusis, and otic discharge in patients who have impaired mucocutaneous immunity, such as patients with chronic eczema (Chapter 405), hypogammaglobulinemia (Chapter 231), diabetes mellitus (Chapter 210), or HIV infection (Chapter 358), as well as patients who are receiving corticosteroids. *Aspergillus* may involve the middle ear and extend into the mastoid sinus if the tympanic membrane has been perforated.

Allergic Forms of Aspergillosis

Allergic Bronchopulmonary Aspergillosis

Allergic bronchopulmonary aspergillosis[10] develops most frequently in patients with a history of chronic asthma (Chapter 75) or cystic fibrosis (Chapter 77). Occurring in genetically susceptible patients exposed to specific *Aspergillus* antigens, allergic bronchopulmonary aspergillosis is characterized by episodic airway obstruction, fever, eosinophilia, positive sputum cultures, mucous plugs containing hyphae, the presence of grossly visible brown flecks in sputum (hyphae), transient infiltrates and parallel "tramline" or ring markings on chest radiographs, proximal bronchiectasis, upper lobe contraction, and elevated levels of total immunoglobulins G and E (IgG and IgE). Eosinophilia may be present in blood, sputum, and lung tissue. Mucous plugs contribute to the development of pulmonary infiltrates, atelectasis, and peribronchial inflammation. The parallel or ring markings are caused by thickened ectatic bronchi, whereas the upper lobe changes are due to progressive apical fibrosis. Pulmonary infiltrates in allergic bronchopulmonary aspergillosis may be nonsegmental and transient in association with eosinophilia and asthma; alternatively, they may be segmental and associated with bronchial obstruction by mucous plugs, wherein asthma and eosinophilia may be absent.

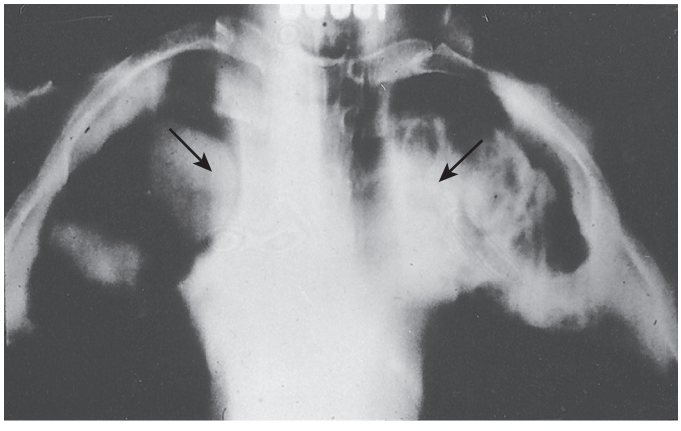

FIGURE 311-1. Tomogram of pulmonary aspergillomas (*arrows*).

Extrinsic Allergic Alveolitis

Extrinsic allergic alveolitis is an unusual allergic form of *Aspergillus* lung disease that is most frequently associated with *Aspergillus clavatus* in malt workers. A hypersensitivity pneumonitis with dyspnea and fever develops approximately 4 hours after exposure. Diffuse reticulonodular interstitial infiltrates may be present at the time of symptoms. Patients have IgG precipitins and cell-mediated immune reactions against *Aspergillus* antigens. Granulomas are present in lung tissue. In contrast to allergic bronchopulmonary aspergillosis, eosinophilia is not a feature of *Aspergillus* extrinsic allergic alveolitis.

Allergic *Aspergillus* Sinusitis

Allergic *Aspergillus* sinusitis is a noninvasive form of sinus disease that typically presents in patients with asthma, nasal polyps, sinus opacification, and eosinophilia. Sinus aspirate yields mucinous material containing eosinophils, Charcot-Leyden crystals (eosinophil-derived rhomboid crystals of galectin-10), and hyphal elements. Allergic *Aspergillus* sinusitis and allergic bronchopulmonary aspergillosis may coexist in some patients. Advanced forms of allergic *Aspergillus* sinusitis may present with proptosis and optic neuropathy that require prompt surgical intervention.

DIAGNOSIS

Invasive Aspergillosis

Diagnosis of invasive pulmonary aspergillosis and disseminated aspergillosis is difficult[11] because no clinical manifestations are pathognomonic. Nevertheless, characteristic computed tomographic (CT) scan features include nodules, halo signs, wedge-shaped infiltrates, and air-crescent signs during invasive pulmonary aspergillosis in immunocompromised patients (Fig. 311-2). For example, infarct-shaped consolidations and smooth bronchial wall thickening are more frequent in invasive pulmonary aspergillosis, whereas mass-shaped consolidations and centrilobular nodules (<10 mm, clustered) are more frequent in tuberculosis (Chapter 299). However, infections caused by *Fusarium* species, *Scedosporium* species, the Mucorales (Chapter 312), and *Pseudomonas aeruginosa* (Chapter 282) may be radiologically indistinguishable from invasive pulmonary aspergillosis.

Microbiologic confirmation is important to differentiate aspergillosis from tuberculosis and from other filamentous fungal infections. Specimens can be

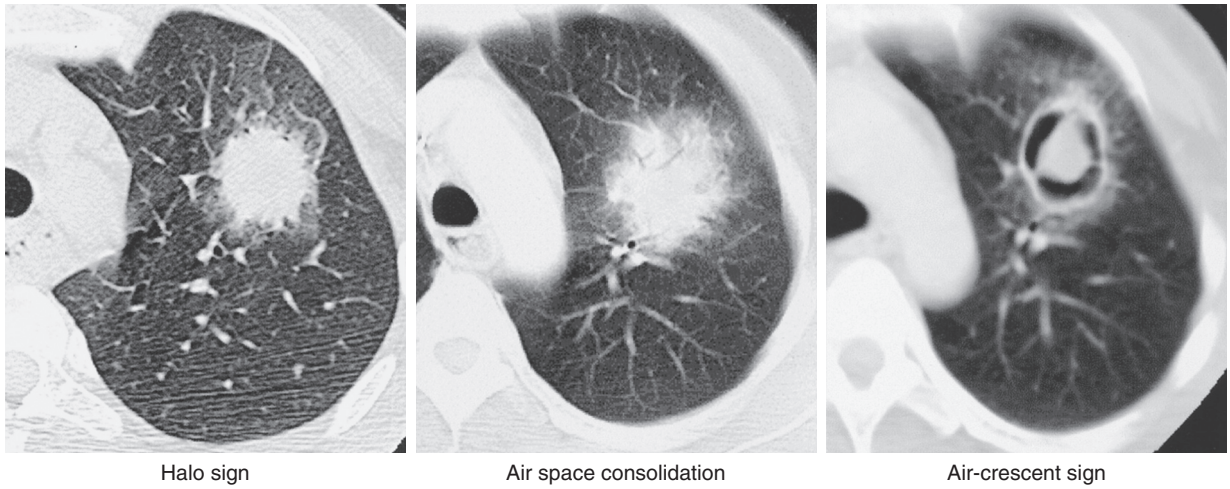

FIGURE 311-2. Evolution of radiography of invasive aspergillosis in an immunocompromised host. D = days after the lesion is first noted.

obtained from bronchoalveolar lavage, percutaneous needle aspiration, video-assisted thoracoscopic (VATS) biopsy, and, if necessary, open lung biopsy. Dichotomously branching septate hyphae may be seen by direct microscopy, or *Aspergillus* species may grow in culture. Both microscopy and culture are highly specific, so a positive finding carries a high probability for diagnosis of invasive aspergillosis, but neither is very sensitive for finding the organism.

Alternative options[12,13] include polymerase chain reaction (PCR)[14] testing, detection of galactomannan by enzyme immunoassay[15] in serum, or bronchoalveolar lavage. The combined use of diagnostic imaging, microscopy, culture, PCR, and cell wall biomarkers in patients with compatible clinical manifestations can hasten the diagnosis of invasive aspergillosis and guide the early initiation of therapy.[A1] Diagnostic criteria for invasive pulmonary aspergillosis include compatible clinical and radiologic features in a susceptible host as well as microbiologic evidence of *Aspergillus* (i.e., positive PCR, positive cultures, an elevated galactomannan level).

Diagnosis of locally invasive extrapulmonary aspergillosis causing mucocutaneous lesions, osteomyelitis, and septic arthritis is best accomplished with biopsy, direct microscopy, PCR, and culture. A diagnosis of *Aspergillus* keratitis is established by direct examination, culture, and, occasionally, PCR of corneal lesions by an ophthalmologist.

Allergic Forms of Aspergillosis

Bronchopulmonary Aspergillosis

Diagnosis of allergic bronchopulmonary aspergillosis is based on the presence of a combination of clinical, biologic, and radiologic criteria (Fig. 311-3). A biphasic skin test response may assist in the diagnosis. A scratch test with *Aspergillus* antigens produces an immediate wheal-and-flare reaction that is mediated by IgE and blocked by antihistamines but not by corticosteroids. An intracutaneous test with the antigens produces a later (6 to 8 hours) reaction that is mediated by IgG and complement and blocked by corticosteroids.

For patients who do not have cystic fibrosis, criteria for allergic bronchopulmonary aspergillosis include asthma, an immediate cutaneous reaction to *A. fumigatus* antigen, a total serum IgE concentration higher than 1000 ng/mL, elevated *A. fumigatus*–specific serum IgE levels, precipitating serum antibodies to *A. fumigatus*, central bronchiectasis, peripheral blood eosinophilia, and characteristic pulmonary infiltrates. The latter two features (eosinophilia and pulmonary infiltrates) are considered nonessential because they only may be present during an acute phase of allergic bronchopulmonary aspergillosis.

For patients with cystic fibrosis (Chapter 77), distinguishing between allergic bronchopulmonary aspergillosis and an episode of clinical deterioration with colonization by *Aspergillus* species is challenging. The current criteria are clinical deterioration (coughing, wheezing, increased sputum production, decreased exercise intolerance, and decrease in pulmonary function); immediate hypersensitivity to *A. fumigatus* (positive skin test or IgE response); total serum IgE concentration higher than 1000 ng/mL; precipitating antibodies to *A. fumigatus*; abnormal chest radiograph (central bronchiectasis); mucous plugs; or unexplained changes compared with previous chest radiographs).

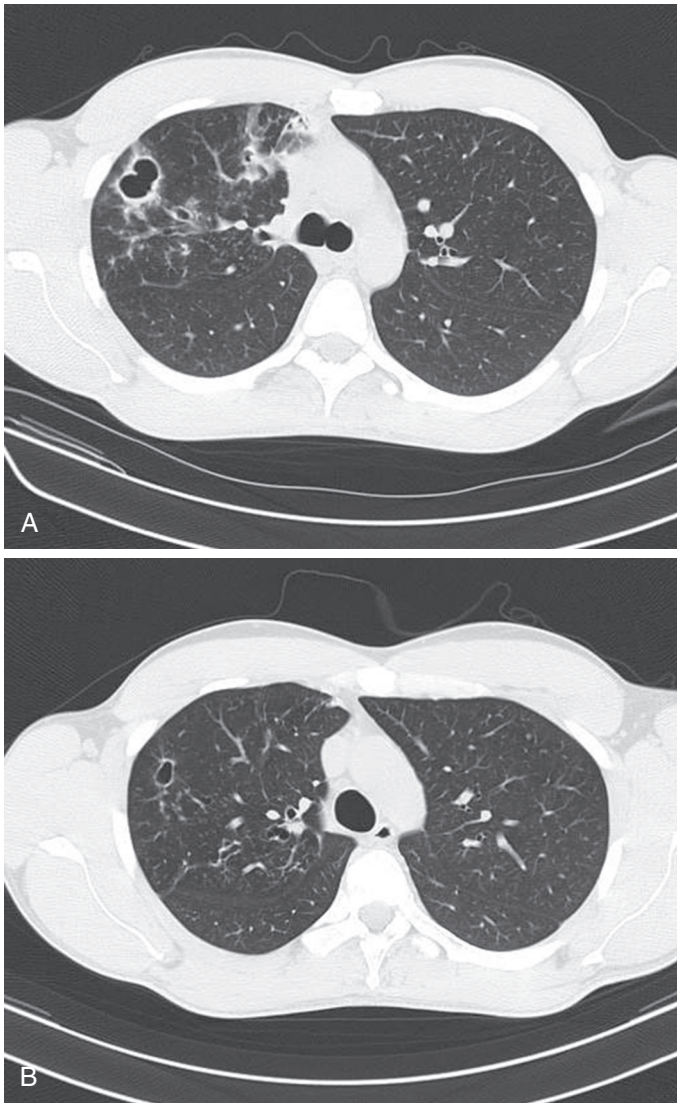

FIGURE 311-3. Allergic bronchopulmonary aspergillosis in a patient with a long history of asthma. A, A thin-slice computed tomographic image showing bronchiectasis with cystic changes in the right upper lobe. This patient had an underlying history of asthma and a markedly elevated immunoglobulin E level and other findings consistent with allergic bronchopulmonary aspergillosis. **B,** The same patient after treatment with systemic steroids; the cystic bronchiectasis has markedly improved. (Courtesy of Anne E. O'Donnell, MD.)

Other Allergic Forms

For extrinsic allergic alveolitis, an occupational history of exposure is critical to the diagnosis. A typical history of recurrent episodes developing within 24 hours after inhalation of conidial antigens in an agricultural environment, in conjunction with a negative scratch test, a positive intradermal test, and granulomas with immunoglobulins and complement in tissue, is diagnostically consistent with *Aspergillus* extrinsic allergic alveolitis. For allergic *Aspergillus* sinusitis, a sinus aspirate yielding mucinous material containing eosinophils, Charcot–Leyden crystals, and hyphal elements establishes the diagnosis.

TREATMENT

Invasive Aspergillosis

The foundation of treatment of invasive aspergillosis consists of three interventions: antifungal medical therapy (Table 311-2); reversal of immunosuppression; and, where appropriate, surgical resection of infected lesions.[16–18]

Antifungal Agents

Voriconazole or isavuconazole is recommended in most patients for the primary treatment of invasive aspergillosis, including pulmonary, disseminated, and extrapulmonary isolated infection. The recommendation for voriconazole is based on a randomized trial showing that voriconazole is superior to deoxycholate amphotericin B (D-AmB) as primary treatment for invasive aspergillosis, as well as extensive clinical experience with the drug. However, voriconazole should not be used in patients with substantially elevated hepatic aminotransferase levels, hepatic dysfunction, a prolonged QTc interval, or a history of intolerance to it. Such patients can be treated with isavuconazole, which is equally effective with fewer drug-related adverse events, more predictable pharmacokinetics, and possibly becoming the treatment of choice. For patients with invasive aspergillosis, posaconazole is an acceptable alternative that is noninferior to voriconazole for all-cause mortality and is less toxic.[A2] Unfortunately, recent emergence of resistance to triazole antifungals (voriconazole, isavuconazole, and posaconazole) may threaten the future utility of the anti-*Aspergillus* triazoles. Another option is liposomal amphotericin B (L-AmB) as primary therapy, based on a randomized trial that demonstrated comparable efficacy of approximately 70% using dosages of 3 mg/kg/day and 10 mg/kg/day of L-AmB in patients who had predominantly hematologic malignancies.

Second-line or salvage antifungal therapy is indicated in patients who are intolerant of or whose infection is unresponsive to primary therapy. Among the antifungal agents used in this setting are a lipid formulation of amphotericin B, posaconazole, or isavuconazole if not used as primary therapy, itraconazole, or an echinocandin (caspofungin is the only agent licensed for this indication). For patients who are already receiving voriconazole, a change of class to a lipid formulation and use of another azole are alternative possibilities. For invasive aspergillosis in patients who have hematologic malignancies and/or have undergone recent allogeneic stem cell transplantation, initial treatment with a combination of voriconazole and anidulafungin[A3] may be associated with reduced all-cause mortality at 6 weeks compared with voriconazole monotherapy. In patients with more extensive infection or risk factors for a poor outcome, combination therapy with voriconazole plus an echinocandin should be considered under the guidance of expert consultants.

TABLE 311-2 ANTIFUNGAL THERAPY OF INVASIVE ASPERGILLOSIS*

FIRST-LINE TREATMENT IN ADULTS†	
Drug of choice:	
Voriconazole	IV therapy: 6 mg/kg q12h for two doses, then 4 mg/kg q12h Oral therapy: 300 mg or 4 mg/kg bid
or	
Isavuconazole	IV or oral therapy: 372 mg (isavuconazonium prodrug) q8h for 6 doses, then 372 mg q24h
Alternate (see text for conditions):	
Liposomal amphotericin B	3-5 mg/kg IV daily
or	
Posaconazole	300 mg PO (delayed-release tablet) or IV q12h day 1, then 300 mg PO or IV daily
SECOND-LINE OR SALVAGE TREATMENT IN ADULTS†	
Amphotericin B lipid complex	5 mg/kg IV daily
or	
Caspofungin	70 mg IV daily for first dose, then 50 mg IV daily
or	
Micafungin	100 mg IV daily
or	
Itraconazole	400 mg PO (capsules) daily (in either one or two doses); or 2.5 mg/kg PO (solution) q12h

*Refer to package insert for dosage modification of antifungal agents in liver disease or renal impairment.

†Duration of antifungal therapy depends on therapeutic response of documented lesions, burden of disease, host immunocompetence, and type of aspergillosis (e.g., acute invasive vs. chronic vs. allergic). Guidelines of Infectious Diseases Society of America recommend at least 6 to 12 weeks for invasive pulmonary aspergillosis. Patients who are immunosuppressed continue treatment throughout the period of immunosuppression and until resolution of lesions. In patients previously diagnosed with invasive aspergillosis, antifungal therapy should be continued or reinitiated during subsequent periods of immunosuppression (e.g., chemotherapy, stem cell transplantation, graft-versus-host disease) to prevent recrudescence.

bid = twice daily; IV = intravenous; PO = orally.

See Patterson T, Thompson GR 3rd, Denning DW, et al. Executive summary: practice guidelines for the diagnosis and management of aspergillosis: 2016 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2016;63:433-442, for more details.

Antifungal therapy for invasive aspergillosis should be continued until lesions have resolved, cultures and biomarkers are negative, and reversible underlying predispositions have abated. Data also support monitoring serum galactomannan levels as a marker for therapeutic response.[19] Reinstating therapy in patients who have previously responded should be considered if immunosuppression is reinstituted or if neutropenia recurs.

Local infusion of antifungal agents, particularly intravitreal therapy of endophthalmitis, provides high concentrations to compartments that may not be reached by systemic therapy. Topical irrigation with voriconazole, amphotericin B, or if available, pimaricin (natamycin) is an important adjunct to the management of *Aspergillus* keratitis.

Reversal of Immunosuppression

Reversal of immunosuppression is a critical factor in the successful management of invasive aspergillosis. Recovery from neutropenia and decreasing the daily dosage or discontinuation of corticosteroids, where feasible, are two of the most important forms of improving host response. Depending on the protocol used, granulocyte transfusions (Chapter 162) may stabilize *Aspergillus* lesions until recovery from neutropenia. Granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) may accelerate recovery from neutropenia (Chapter 153). The role of GM-CSF, G-CSF, or interferon-γ in immunocompromised non-neutropenic patients with invasive aspergillosis remains to be further defined.[20]

Surgery

Surgical management is important for several manifestations of invasive pulmonary aspergillosis: recurrent hemoptysis from a single cavitary lesion, invasion of a pulmonary lesion into the chest wall, and pulmonary lesions contiguous with great vessels or the pericardium. *Aspergillus* empyema requires closed chest tube drainage and possibly débridement of the infected pleural cavity. Débridement of sinus aspergillosis, particularly when the ethmoid and frontal sinuses are infected, may prevent extension into the orbit or into the cavernous sinus. Surgical resection of selected CNS lesions, depending on their location and the clinical manifestations they cause, may be indicated for establishing a diagnosis, reducing increased intracranial pressure, and/or protecting critical neural centers. Surgical management of infected lesions also is an important adjunctive component of primary therapy for several forms of invasive nonpulmonary aspergillosis: endocarditis, pericarditis, osteomyelitis, epidural abscess, infected vascular catheters and prosthetic devices, and skin and soft tissue infection.

Chronic Aspergillosis

Antifungal Agents

Medical therapy has limited benefit in the treatment of aspergilloma, but some patients may benefit from extended use of an antifungal triazole (voriconazole, posaconazole, or isavuconazole in doses outlined for invasive pulmonary aspergillosis [see earlier]). For example, 12 months of oral itraconazole can reduce clinical relapses from about 40% to about 10% compared with 6 months of therapy, but without any difference in death rates.[A4] Lifelong commitment to an antifungal triazole should be balanced against the natural history of approximately 10% of aspergillomas resolving spontaneously. By comparison, medical therapy with itraconazole or voriconazole is the standard of treatment for chronic cavitary pulmonary aspergillosis. Patients with chronic cavitary pulmonary aspergillosis typically achieve improvement of symptoms and stabilization or improvement of radiologic changes. Patients with chronic necrotizing pulmonary aspergillosis also should receive an antifungal triazole, but assessment of response is more difficult because of the underlying chronic lung disease.

Interventional Therapy

The role of surgical resection in patients with solitary aspergilloma or chronic cavitary pulmonary aspergillosis is limited because of development of bronchopleural fistula, *Aspergillus* infection of the pleural space, and potentially further worsening of already compromised pulmonary function. However, surgical resection may have a more important role in treating patients with recurrent and severe hemoptysis, for which the benefits of removing the cavity usually outweigh the known risks. Bronchial artery embolization and transthoracic direct intracavitary instillation of antifungal agents for aspergilloma have only limited benefits[A5] but substantial risk.

Otomycosis

Topical irrigating solutions of boric acid, acetic acid, or an antifungal azole cream may be effective in treating *Aspergillus* otomycosis. Voriconazole, posaconazole, or itraconazole may be necessary for refractory cases or perforated tympanic membranes.

Allergic Forms of Aspergillosis

Allergic bronchopulmonary aspergillosis (Chapter 75) is treated with a combination of corticosteroids and itraconazole (200 mg twice daily orally for 16 weeks). The optimal doses of corticosteroids are unknown but commonly include an initial prednisone dose of 0.5 mg/kg/daily for 2 weeks followed by an every other day dose of 0.5 mg/kg, then tapering off over a 16-week period. Higher doses may be needed in patients with a concomitant asthma flare, but are associated with more side effects.[A6] Voriconazole (200 mg twice daily) is another alternative that may be better tolerated than itraconazole.[A7] Intermittent use of corticosteroids or substantially raising the dose in patients who are receiving chronic therapy can produce rapid resolution of intercurrent symptomatic episodes. At this time there is a lack of evidence for the efficacy and safety of anti-IgE (omalizumab and dupilumab) therapy in patients with allergic bronchopulmonary aspergillosis and cystic fibrosis and in other non–cystic fibrosis patients.[A8]

Extrinsic allergic alveolitis is best managed by removing patients from the allergenic environment. An accurate occupational and home environment history is critical to this intervention.

Allergic *Aspergillus* sinusitis is treated by endoscopic drainage to relieve obstruction by tenacious mucin. Itraconazole and systemic steroids in regimens as described earlier, or nasal corticosteroids, alone or in combination, may be beneficial in some patients with allergic *Aspergillus* sinusitis. Caution is warranted with chronic use of systemic or nasal corticosteroids. Itraconazole may have a corticosteroid-sparing effect.

PREVENTION

Several strategies may be used for prevention of invasive aspergillosis in immunocompromised patients: primary prophylaxis, empirical therapy, and secondary prophylaxis. In patients undergoing stem cell transplantation and in patients with acute myelogenous leukemia or myelodysplastic syndromes, posaconazole prophylaxis (200 mg by suspension three times daily) can significantly reduce invasive fungal infections more effectively than either fluconazole or itraconazole and also improves overall survival.[A9] Posaconazole suspension is poorly absorbed and not well tolerated so that its use has been replaced by posaconazole extended-release tablets at 300 mg orally per day. Empirical antifungal therapy, either routine or guided by the depth and duration of neutropenia,[A10,A11] provides early treatment for persistently febrile immunocompromised patients and systemic antifungal prophylaxis in doses as described earlier for high-risk hosts with or without pulmonary infiltrates. L-AmB, caspofungin, micafungin, posaconazole, and voriconazole (see Table 311-2) have been used for this strategy. Secondary prophylaxis of invasive aspergillosis with voriconazole at doses described earlier is used for patients who have a history of previous aspergillosis and who are scheduled for a subsequent cycle of immunosuppression that may increase the risk for recurrence.

Reduction of exposure to airborne conidia, such as by HEPA filtration of hospital air, avoiding activities that increase conidial aerosols (room maintenance,

dust exposures, and contaminated materials [e.g., potted plants]), as well as providing clean water distribution systems, may reduce acquisition of *Aspergillus* by immunosuppressed or neutropenic patients.

For patients with allergic forms of aspergillosis, use of corticosteroids and itraconazole, alone or in combination, may prevent debilitating exacerbations. The toxicity of chronic administration of prednisone warrants strategies for intermittent administration of prednisone or corticosteroid-sparing use of itraconazole. Aerosolized antifungal agents are a promising option to prevent exacerbations of allergic bronchopulmonary aspergillosis.

PROGNOSIS

Untreated invasive aspergillosis is associated with severe morbidity and high mortality in immunocompromised patients. For example, the mortality of acute invasive aspergillosis in recipients of stem cell transplants varies from close to 100% with CNS infection or endocarditis to approximately 65% with pulmonary infection. Early recognition of clinical manifestations followed by prompt initiation of empiric antifungal therapy may improve the ominous prognosis of acute invasive aspergillosis, especially if accompanied by reversal of immunosuppression and successful treatment of the underlying primary disease. For patients with chronic aspergillosis, including allergic bronchopulmonary aspergillosis, multidisciplinary specialized supportive care may improve outcome and quality of life.

312 MUCORMYCOSIS

DIMITRIOS P. KONTOYIANNIS AND LUIS OSTROSKY-ZEICHNER

DEFINITION

Mucormycosis is the unifying term used to describe infections caused by fungi belonging to the order Mucorales. Mucorales typically cause aggressive, acute-onset, frequently fatal or disfiguring, angioinvasive infections, especially in immunosuppressed hosts.

EPIDEMIOLOGY

Mucorales fungi are distributed worldwide and found in decaying organic substrates. The true incidence of mucormycosis is not known and probably is underestimated because of difficulties in antemortem diagnosis. The most common microbiologically confirmed infecting species are *Rhizopus* (about 50% of cases); and *Mucor* (about 20% of cases), but other species include *Cunninghamella bertholletiae*, *Apophysomyces elegans*, *Absidia*, *Saksenaea*, and *Rhizomucor pusillus*. *Apophysomyces* is predominant in Asia, and *Lichtheimia* species predominate in Europe. The thermophilic Mucorales *Saksenaea vasiformis elegans* caused necrotizing soft tissue infections in victims of combat-related injuries in Afghanistan. *Apophysomyces elegans* were implicated in victims of the Joplin tornado in 2011, and a major mucormycosis outbreak in coronavirus disease 2019 (COVID-19) patients in India[1,2] was attributable to *Apophysomyces* and *Rhizomucor* species. Worldwide, COVID-19 infection has been associated with an increased incidence of mucormycosis, primarily but not exclusively in the nasopharynx.[3]

The classic risk factors for mucormycosis include hematologic malignancy, hematopoietic stem cell or solid organ transplantation, poorly controlled diabetes mellitus, chronic acidemia, prematurity, profound chronic debilitation, trauma, burns, and, very rarely, intravenous drug use.[4] Nosocomial cutaneous infections related to contaminated materials or fomites can develop at sites of surgical wounds or intravenous catheter insertion. Breakthrough mucormycosis also is observed when patients with leukemia and recipients of hematopoietic stem cell transplants receive *Aspergillus*-active drugs without anti-Mucorales activity (e.g., voriconazole).

PATHOBIOLOGY

Mucorales species are saprophytic, rapidly growing fungi. Angioinvasive growth that results in infarction and necrosis of surrounding tissue is the hallmark of mucormycosis. The major modes of transmission are inhalation, ingestion, and direct inoculation, with inhalation of spores from environmental sources being the most common. Cutaneous or percutaneous transmission with traumatic disruption of skin barriers is the most important mode of transmission in immunocompetent hosts. Gastrointestinal acquisition, although less common, has occurred in patients who repeatedly ingest spores in the setting of severe malnutrition; ingestion of non-nutritional substances (pica); and contaminated herbal, homeopathic, or medicinal products.

Host immunity in healthy hosts prevents germination of fungal spores unless the inoculum is heavy. To establish invasive infection, spores must overcome both innate and adaptive immune responses to germinate into hyphae. Defects in phagocytic activity (e.g., neutropenia) and functional defects (e.g., caused by glucocorticoids, hyperglycemia, and/or acidosis) allow unimpeded proliferation of fungi because of the absence of a coordinated, effective host response.[5] *Rhizopus* interacts with glucose-regulated protein 78 (GRP78) on nasal epithelial cells via its spore coat protein CotH3 to invade and damage the nasal epithelial cells. Both GRP78 and CotH3 are upregulated in the acidemic hyperglycemic environment. Mucorales also produce a ricin-like toxin, called mucoricin, which can inhibit protein synthesis and increase its virulence.[6] Mucormycosis is often disseminated in severely immunosuppressed patients, with high mortality rates.

Free iron is an essential component of the pathogenesis of mucormycosis, and patients with iron overload are predisposed to such infections, especially if they are being treated with deferoxamine to chelate iron. *Rhizopus oryzae* can utilize deferoxamine as a xenosiderophore to form a ferrioxamine complex and to obtain more iron for use.

Poorly controlled diabetes mellitus, which is a major predisposing factor, is reported in 36 to 88% of all cases of mucormycosis. In particular, diabetic patients with ketoacidosis are susceptible to mucormycosis. Normal human serum cannot support the growth of *R. oryzae*, whereas serum in diabetic patients can do so. Acidosis disrupts the normal inhibitory activity of serum by attenuating the ability of transferrin to bind iron from the fungus. In addition, quantitative and qualitative neutrophilic and phagocytic cell dysfunction in diabetic patients with ketoacidosis may play a role in the pathogenesis of mucormycosis.

CLINICAL MANIFESTATIONS

The clinical presentation of mucormycosis depends on the host's underlying immunologic status and medical condition.[7] Patients often have indolent clinical presentations until extensive invasion or dissemination occurs.

Infectious syndromes associated with Mucorales are grouped based on clinical presentation into one of six categories: rhinocerebral (about 76% of cases); cutaneous (about 8.5% of cases); pulmonary (about 7.5% of cases); gastrointestinal; disseminated; and unusual presentations.[8]

312 MUCORMYCOSIS

DIMITRIOS P. KONTOYIANNIS AND LUIS OSTROSKY-ZEICHNER

DEFINITION

Mucormycosis is the unifying term used to describe infections caused by fungi belonging to the order Mucorales. Mucorales typically cause aggressive, acute-onset, frequently fatal or disfiguring, angioinvasive infections, especially in immunosuppressed hosts.

EPIDEMIOLOGY

Mucorales fungi are distributed worldwide and found in decaying organic substrates. The true incidence of mucormycosis is not known and probably is underestimated because of difficulties in antemortem diagnosis. The most common microbiologically confirmed infecting species are *Rhizopus* (about 50% of cases); and *Mucor* (about 20% of cases), but other species include *Cunninghamella bertholletiae*, *Apophysomyces elegans*, *Absidia*, *Saksenaea*, and *Rhizomucor pusillus*. *Apophysomyces* is predominant in Asia, and *Lichtheimia* species predominate in Europe. The thermophilic Mucorales *Saksenaea vasiformis elegans* caused necrotizing soft tissue infections in victims of combat-related injuries in Afghanistan. *Apophysomyces elegans* were implicated in victims of the Joplin tornado in 2011, and a major mucormycosis outbreak in coronavirus disease 2019 (COVID-19) patients in India[1,2] was attributable to *Apophysomyces* and *Rhizomucor* species. Worldwide, COVID-19 infection has been associated with an increased incidence of mucormycosis, primarily but not exclusively in the nasopharynx.[3]

The classic risk factors for mucormycosis include hematologic malignancy, hematopoietic stem cell or solid organ transplantation, poorly controlled diabetes mellitus, chronic acidemia, prematurity, profound chronic debilitation, trauma, burns, and, very rarely, intravenous drug use.[4] Nosocomial cutaneous infections related to contaminated materials or fomites can develop at sites of surgical wounds or intravenous catheter insertion. Breakthrough mucormycosis also is observed when patients with leukemia and recipients of hematopoietic stem cell transplants receive *Aspergillus*-active drugs without anti-Mucorales activity (e.g., voriconazole).

PATHOBIOLOGY

Mucorales species are saprophytic, rapidly growing fungi. Angioinvasive growth that results in infarction and necrosis of surrounding tissue is the hallmark of mucormycosis. The major modes of transmission are inhalation, ingestion, and direct inoculation, with inhalation of spores from environmental sources being the most common. Cutaneous or percutaneous transmission with traumatic disruption of skin barriers is the most important mode of transmission in immunocompetent hosts. Gastrointestinal acquisition, although less common, has occurred in patients who repeatedly ingest spores in the setting of severe malnutrition; ingestion of non-nutritional substances (pica); and contaminated herbal, homeopathic, or medicinal products.

Host immunity in healthy hosts prevents germination of fungal spores unless the inoculum is heavy. To establish invasive infection, spores must overcome both innate and adaptive immune responses to germinate into hyphae. Defects in phagocytic activity (e.g., neutropenia) and functional defects (e.g., caused by glucocorticoids, hyperglycemia, and/or acidosis) allow unimpeded proliferation of fungi because of the absence of a coordinated, effective host response.[5] *Rhizopus* interacts with glucose-regulated protein 78 (GRP78) on nasal epithelial cells via its spore coat protein CotH3 to invade and damage the nasal epithelial cells. Both GRP78 and CotH3 are upregulated in the acidemic hyperglycemic environment. Mucorales also produce a ricin-like toxin, called mucoricin, which can inhibit protein synthesis and increase its virulence.[6] Mucormycosis is often disseminated in severely immunosuppressed patients, with high mortality rates.

Free iron is an essential component of the pathogenesis of mucormycosis, and patients with iron overload are predisposed to such infections, especially if they are being treated with deferoxamine to chelate iron. *Rhizopus oryzae* can utilize deferoxamine as a xenosiderophore to form a ferrioxamine complex and to obtain more iron for use.

Poorly controlled diabetes mellitus, which is a major predisposing factor, is reported in 36 to 88% of all cases of mucormycosis. In particular, diabetic patients with ketoacidosis are susceptible to mucormycosis. Normal human serum cannot support the growth of *R. oryzae*, whereas serum in diabetic patients can do so. Acidosis disrupts the normal inhibitory activity of serum by attenuating the ability of transferrin to bind iron from the fungus. In addition, quantitative and qualitative neutrophilic and phagocytic cell dysfunction in diabetic patients with ketoacidosis may play a role in the pathogenesis of mucormycosis.

CLINICAL MANIFESTATIONS

The clinical presentation of mucormycosis depends on the host's underlying immunologic status and medical condition.[7] Patients often have indolent clinical presentations until extensive invasion or dissemination occurs.

Infectious syndromes associated with Mucorales are grouped based on clinical presentation into one of six categories: rhinocerebral (about 76% of cases); cutaneous (about 8.5% of cases); pulmonary (about 7.5% of cases); gastrointestinal; disseminated; and unusual presentations.[8]

ABSTRACT

Mucormycoses describe a spectrum of chronic, subacute, and rapidly progressing infections caused by the fungi Mucorales. Clinical presentations, which are pleiotropic, include sinusitis (pansinusitis, rhino-orbital, or rhinocerebral), pulmonary, cutaneous, gastrointestinal, disseminated, and other uncommon presentations. Mucormycosis is typically seen following extensive trauma, in patients with uncontrolled diabetes, and in the setting of severe and prolonged immune suppression. In heavily immunocompromised patients, Mucorales have proclivity for angioinvasion, thereby resulting in tissue infarction, necrosis, and dissemination. Diagnosis requires a high index of clinical suspicion based on risk factors, clinical and radiologic presentation, and biopsy for histopathology and culture of the affected areas. Noninvasive rapid diagnostic tests are lacking. Reversal of immunosuppression and control of underlying metabolic abnormalities are important pillars of therapy, along with surgery and appropriate early antifungal agents. Despite the recent introduction of mold-active oral triazoles (posaconazole and isavuconazole) in addition to amphotericin B products, no randomized trials are available to guide therapy. Aggressive surgical resection of necrotic tissue is critical, especially in localized infection. Delayed diagnosis and the degree of immunosuppression are key determinants for poor outcome.

KEYWORDS

mucormycosis
Mucorales fungi
rhinocerebral mucormycosis
pulmonary mucormycosis
gastrointestinal mucormycosis
posaconazole
isavuconazole
amphotericin B

Rhino-orbital or rhinocerebral mucormycosis is the characteristic presentation in patients with diabetic ketoacidosis. Cutaneous mucormycosis is seen in both immunocompetent and immunocompromised hosts, typically following local trauma or burns that compromise skin integrity or after subcutaneous tissue injuries. Pulmonary mucormycosis is most common in neutropenic or corticosteroid-treated patients (e.g., hematopoietic stem cell and solid organ transplant recipients).

Rhinocerebral Mucormycosis

Rhinocerebral mucormycosis, which is the most common infectious manifestation, originates in the paranasal sinuses after inhalation of Mucorales spores and then extends to the orbit (sino-orbital) or brain (rhinocerebral), particularly in patients who have diabetic ketoacidosis or profound neutropenia.[9] Early signs and symptoms of sinus invasion (sinus pain, congestion, headache, mouth pain, otologic symptoms, and hypo-osmia/anosmia) may be indistinguishable from common causes of sinusitis (Chapter 394). Involved tissues become red, then violaceous, and finally black due to thrombosis and tissue necrosis. Signs of extensive, rapidly progressing infection include necrotic eschar of the nasal cavity and turbinates, facial lesions, and exophytic or necrotic lesions of the hard palate. A painful black eschar on the palate or nasal mucosa is a classic diagnostic but late sign, and its absence does not exclude rhinocerebral infection because necrotic nasal or palatal lesions are seen in only 50% of patients within 3 days of onset of infection. Signs and symptoms of periorbital and orbital involvement, which may be seen when the patient first presents, include periorbital swelling, preseptal and/or orbital cellulitis, proptosis, chemosis, blurred vision or rapidly progressing external ophthalmoplegia, diplopia, eyelid gangrene, retinal detachment, and endophthalmitis. Patients with extensive rhino-orbital or rhinocerebral disease also may present with trigeminal or other cranial nerve palsy, which is consistent with perineural invasion. Infection can rapidly progress through the cavernous sinuses into the central nervous system, thereby resulting in cavernous sinus and internal carotid artery thrombosis. A bloody nasal discharge may be the only sign indicating that the infection has invaded through the nasal turbinates and into the brain. Patients with advanced infection also may have altered consciousness, bone destruction, frontal lobe necrosis, epidural and subdural abscesses, and/or basilar artery aneurysm.

Skin and Soft Tissue Mucormycosis

Cutaneous mucormycosis, which typically occurs in victims of severe skin or muscular injury or in postoperative patients,[10] usually starts as erythema and skin induration at a puncture site and progresses to necrosis with a black eschar. Cutaneous infections can quickly extend into the deep fascia and muscle. Neutropenic patients in particular are susceptible to lymphatic and blood vessel invasion, infarction, and necrosis with eventual dissemination. Skin lesions in patients with suspected mucormycosis should raise concerns about disseminated disease and prompt careful clinical evaluation.

Pulmonary Mucormycosis

The clinical manifestations of pulmonary mucormycosis are indistinguishable from those of invasive pulmonary aspergillosis (Chapter 311).[11] Fever refractory to broad-spectrum antibiotics, nonproductive cough, and progressive dyspnea are the most common presenting symptoms.[12] Less commonly, pleuritic chest pain, hemoptysis, and pleural effusion are seen. If the major pulmonary blood vessels are invaded by fungal hyphae, massive and potentially fatal hemoptysis can occur. Clues for distinguishing pulmonary mucormycosis from invasive pulmonary aspergillosis include the presence of pansinusitis, a history of prophylaxis with antifungals against *Aspergillus* but not Mucorales (e.g., voriconazole, echinocandins), and possibly continual absence of detectable *Aspergillus galactomannan* antigen in serum. In rare circumstances, pulmonary mucormycosis can present as an endobronchial or tracheal lesion with a less fulminant course, especially in diabetics. Tracheobronchial mucormycosis may cause airway obstruction or erosion of major pulmonary blood vessels and fatal hemoptysis.

In immunocompetent hosts, pulmonary mucormycosis may present with more atypical, slowly progressing manifestations. As with *Aspergillus* species, Mucorales can form mycetomas in preexisting lung cavities and cause slowly necrotizing pneumonia and hypersensitivity syndromes.

Gastrointestinal Mucormycosis

Symptoms and signs of gastrointestinal mucormycosis include fever, abdominal distention, nausea, vomiting, abdominal pain, diarrhea, melena, hematemesis, hematochezia, and masslike appendiceal and ileal lesions. Primary gastrointestinal mucormycosis, which is rare, can present as necrotizing enterocolitis and involve any part of the alimentary tract, primarily in malnourished patients but also in immunocompetent hosts.[13] The liver, spleen, and pancreas also can be involved. Liver abscesses can occur following ingestion of herbal products contaminated by *Mucor indicus*. Fungi can invade the bowel wall and blood vessels, thereby resulting in bowel perforation, peritonitis, and massive gastrointestinal hemorrhage. Secondary gastrointestinal involvement results from seeding of the gastrointestinal tract, especially in neutropenic patients.

Disseminated Mucormycosis

Disseminated mucormycosis is rarely apparent antemortem. Severely immunosuppressed patients (e.g., patients with prolonged and profound neutropenia, allogeneic stem cell transplant recipients with severe graft-versus-host disease) and patients receiving deferoxamine iron chelation therapy are at the highest risk. Symptoms vary depending on the site of dissemination and degree of vascular infarction of the affected organs. The most common source of dissemination is the lung, and the most common site of spread is the brain.

Rare Clinical Presentations of Mucormycosis

Mucormycosis has protean manifestations that can involve any organ. Isolated cases of tracheal, mediastinal, bone, heart, kidney, otitis externa, and corneal involvement occur. Cerebral mucormycosis, often presenting as brain abscess involving the basal ganglia, has been typically observed in conjunction with infective endocarditis in patients using intravenous drugs.[14] Peritonitis can rarely occur in patients undergoing continuous ambulatory peritoneal dialysis.

DIAGNOSIS

The clinical signs and symptoms of local and disseminated mucormycosis are nonspecific, so a high level of suspicion is of paramount importance in susceptible patients.[15,16] Rapid diagnosis is critical because virtually all patients with disseminated mucormycosis die without rapid diagnosis and treatment.

Radiology

For suspected rhinocerebral mucormycosis, accurate diagnosis and prompt medical and surgical intervention are critical because of the rapid progression of the infection. Computed tomography (CT) and magnetic resonance imaging (MRI) can reveal soft tissue involvement around the nerve sheaths as well as bone destruction. CT frequently shows mucosal thickening, air-fluid levels, and bony erosion. Orbital thickening may be detected earlier by using MRI. CT and MRI scans of the orbits may be unremarkable during the initial stages of mucormycosis, thereby highlighting the importance of serial imaging. Extraorbital muscle thickening, which is often the first sign of orbital involvement, should prompt empirical antifungal therapy followed by surgical exploration or biopsy.

Pulmonary mucormycosis usually has no specific radiographic findings to distinguish it from other pneumonias, especially other fungal pneumonia. However, pulmonary mucormycosis can progress and invade adjacent organs by traversing tissue planes, including the diaphragm, chest wall, and pleura (Fig. 312-1).

Clinical Specimens

Biopsy and culture from sterile sites are critical, because tissue swabs and cultures of sputum, sinus secretions, and bronchoalveolar lavage fluid are usually nondiagnostic. Clinical specimens can be contaminated, so growth in culture may not represent clinically significant invasive mucormycosis. However, a Mucorales-positive culture and especially repetitive positive cultures are an important indication of infection in immunocompromised patients. Molecular techniques for detecting Mucorales are not widely available but are reported to have a sensitivity of 85% and a specificity of 90%.[17]

For rhinocerebral disease, necrotic lesions should be biopsied and evaluated histologically. For pulmonary disease, diagnosis is usually made by transbronchial biopsy. For necrotic skin lesions, especially in neutropenic patients, biopsy specimens should be obtained from the center of the lesion down to the subcutaneous fat. For potential disseminated disease, biopsy of suspected sites is critical because of the low yield of blood cultures and suboptimal recovery of the fungus from respiratory specimens.

Histopathology

Histopathologic examination of infected tissue typically shows characteristic broad (3 to 25 μm in diameter), thin-walled, primarily aseptate

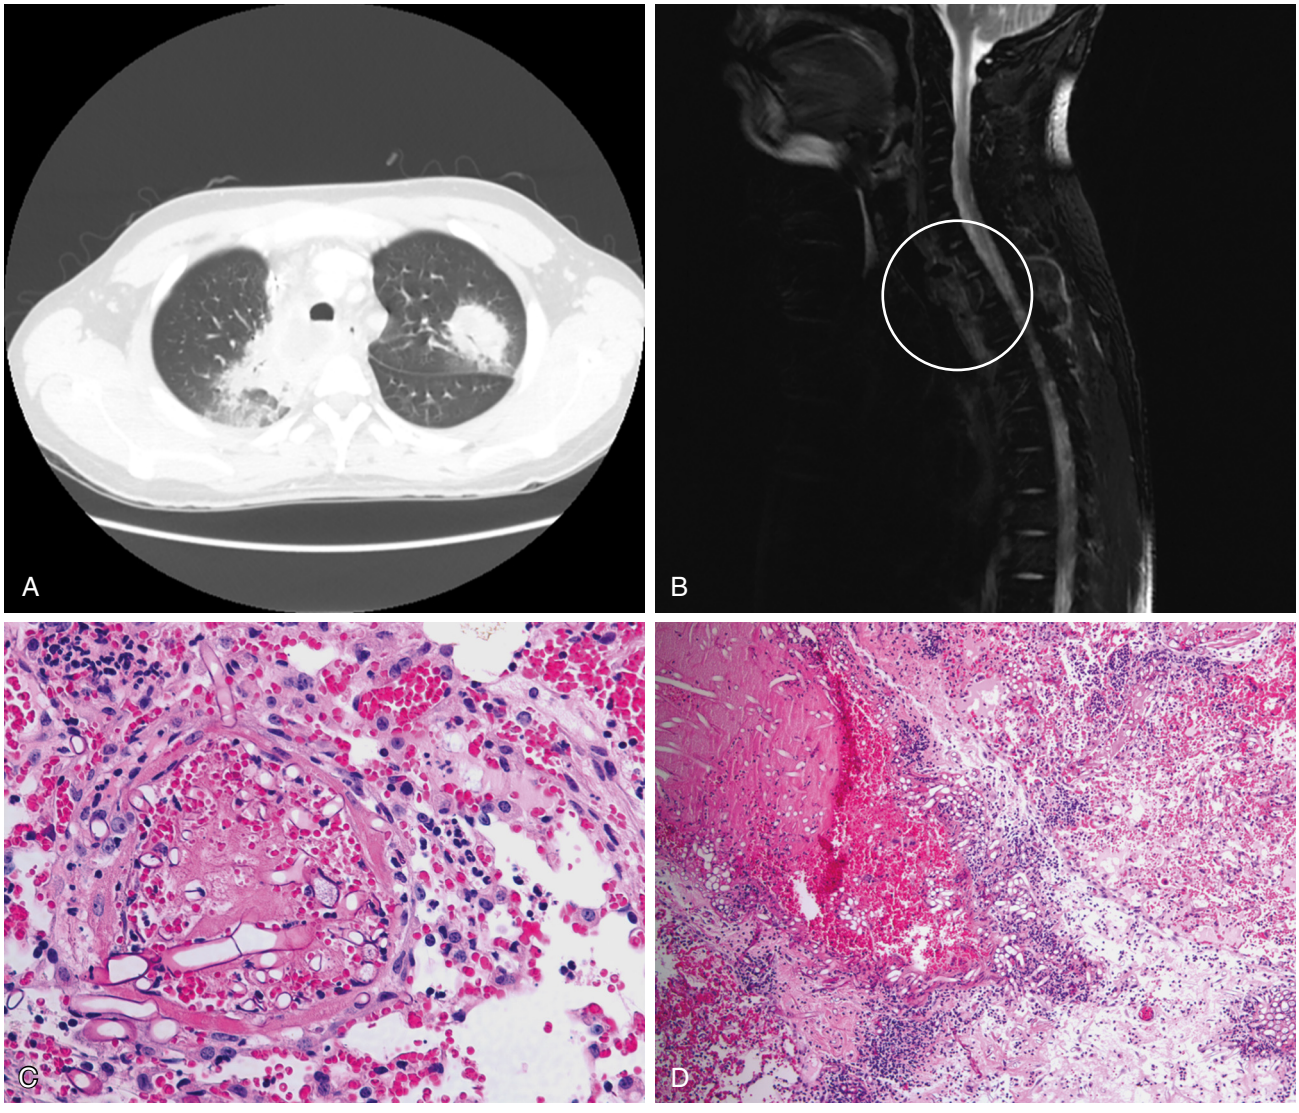

FIGURE 312-1. Extensive, progressive pulmonary mucormycosis in a patient with active leukemia and neutropenia. Characteristic extensions of the infection across tissue planes to trachea (producing a fistula) and mediastinum (**A**) and adjacent spine (**B**) are shown. The histopathologic characteristics of profound necrosis and hemorrhage and pauciseptate, broad-based, ribbon-like Mucorales are also shown (**C** and **D**). Culture of a tissue biopsy specimen remained negative. The patient died 3 weeks after diagnosis, despite aggressive use of a high-dose lipid formulation of amphotericin B (AMB) and adjunct immune therapy.

hyphae; focal bulbous dilation; and nondichotomous irregular branching at occasional right angles accompanying tissue necrosis and fungal angioinvasion (see Fig. 312-1). Perineural invasion is found in 90% of tissues containing nerves. Fungal hyphae can be examined directly using a potassium hydroxide preparation of a tissue specimen or bronchial alveolar lavage fluid. Although contamination is always possible, discovery of fungal elements in a specimen obtained from an immunocompromised host is considered significant.

Culture

Mucorales fungi characteristically produce large, ribbon-like hyphae with irregular diameters and only occasionally septa, thereby resulting in characterization of these organisms primarily as aseptate fungi. Identification can be confirmed by observing the characteristic saclike fruiting structures (sporangia), which produce internally spherical yellow or brown spores (sporangiospores). Spores range from 3 to 11 μm in diameter and are easily aerosolized. Blood cultures are rarely positive for these pathogens despite their angioinvasive nature. Paradoxically, even when fungal hyphae are seen in histopathologic analysis, fungal cultures may not be positive because the friability of nonseptated hyphae make them more susceptible to damage during tissue manipulation. Culture must be performed in a well-qualified laboratory that is knowledgeable about appropriate methods. Data on the antifungal susceptibility of Mucorales species are limited, and minimal inhibitory concentration (MIC) testing is rarely available outside research or reference laboratories.

TREATMENT

Early diagnosis is critical to the outcome, and delayed administration of systemic antifungal therapy increases the probability of death. Successful treatment of mucormycosis relies on a multifaceted strategy (Fig. 312-2) that includes (1) aggressive diagnosis and rapid initiation of effective antifungal therapy, (2) extensive surgical débridement, and (3) rapid control of underlying medical conditions.[18-20]

Antifungal Therapy

Mucorales are resistant to many antifungals, including flucytosine, ketoconazole, fluconazole, voriconazole, and the echinocandins. Also, they have variable susceptibility to itraconazole. Amphotericin B, isavuconazole, and posaconazole are the most active agents in vitro, although their activities differ among different Mucorales families.

Lipid formulations of amphotericin B (liposomal amphotericin B, amphotericin B lipid complex, amphotericin B colloidal dispersion), which are less nephrotoxic and can be given at higher doses (e.g., 5 to 10 mg/kg per day) than standard amphotericin, are the drugs of choice for mucormycosis.[21] Amphotericin B by transthoracic injection or aerosol has been successful in conjunction with concomitant systemic therapy in selected patients with pulmonary mucormycosis. Topical amphotericin B and other polyenes (natamycin) may be effective against primary cutaneous and ocular mucormycosis. Combining an echinocandin (see Chapter 307) with liposomal amphotericin B may be better than liposomal amphotericin B for diabetic patients with rhino-orbital mucormycosis compared with amphotericin B alone, especially in patients with cerebral involvement, but not in patients with underlying hematologic cancer who develop mucormycosis. Isavuconazole (loading dose 372 mg every 8 hours for six doses IV/oral; followed

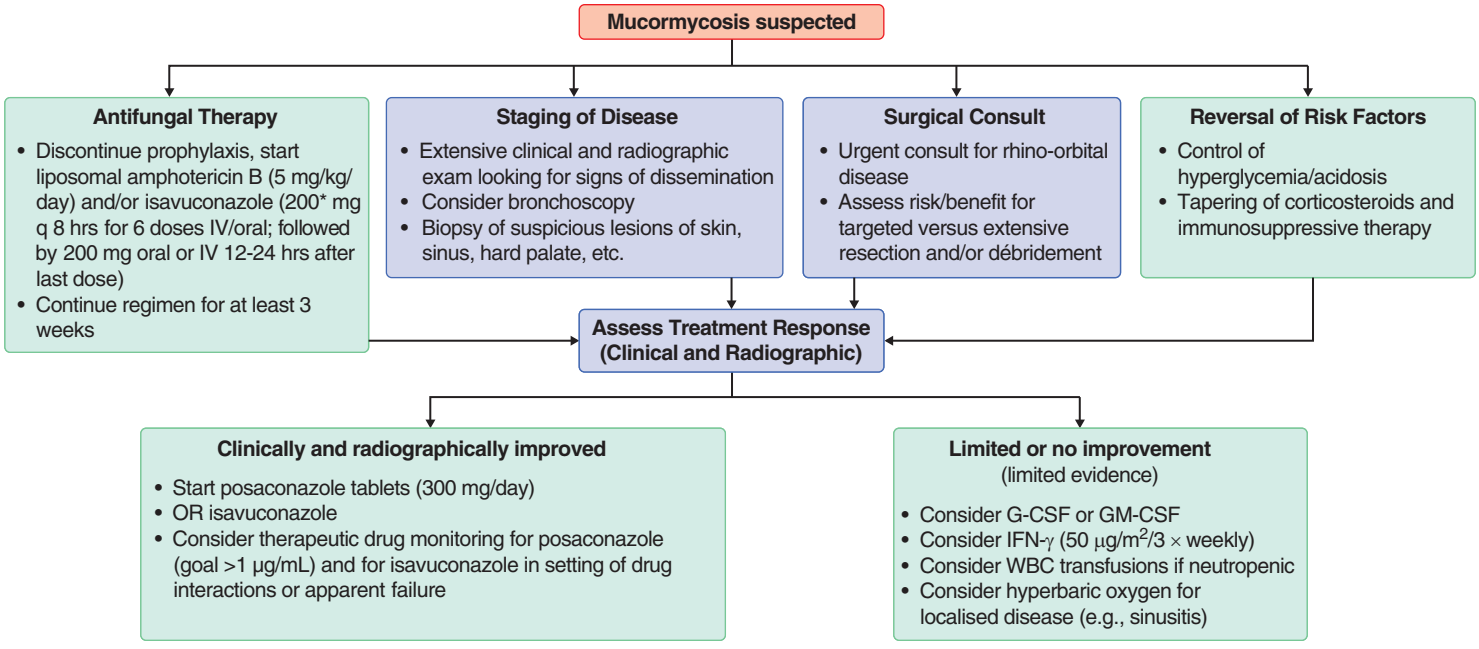

FIGURE 312-2. **Diagram of the management approach to patients with suspected mucormycosis.** *200 mg of isavuconazole = 372 mg of isavuconazonium sulfate. G-CSF = granulocyte-colony stimulating factor; GM-CSF = granulocyte-macrophage-colony stimulating factor; IFN = interferon; IV = intravenous; WBC = white blood count.

by 372 mg oral or IV 12 to 24 hours after the last dose) appears to be as efficacious as amphotericin B in a matched case-control analysis. Posaconazole (800 mg suspension or 300-mg tablet orally daily) can be useful as salvage therapy in patients with refractory mucormycosis, but it is uncertain whether posaconazole alone or combined with a lipid formulation of amphotericin B or other agent (e.g., deferasirox) is of value otherwise.

The duration of antifungal therapy should be determined on an individual basis. Near-normalization of radiographic imaging, negative follow-up biopsy specimens, negative cultures from the affected site, and recovery from immunosuppression are important indicators for stopping antifungal therapy.

Surgery

Because of the aggressively invasive nature of mucormycosis, surgical débridement of cutaneous lesions is crucial and must be done without delay to improve prognosis. Small focal lesions can be surgically resected before they progress to involve critical structures or distal organs. For device-related mucormycosis, prompt removal of the device and several weeks of systemic antifungal therapy are essential for resolution of the infection.

Repeated removal of necrotic tissue or aggressive surgical measures such as enucleation of the eye may be required to control the infection. A CT scan or MRI before surgery and intraoperative frozen section analysis can help guide the extent of the procedure.

Management of Comorbidity and Adjunct Treatments

Rapid correction of underlying conditions, such as control of hyperglycemia, reversal of ketoacidosis, rapid tapering of glucocorticoid therapy, and discontinuation of deferoxamine treatment, can improve outcomes. Hyperbaric oxygen may be a beneficial adjunctive therapy, particularly in diabetic patients with rhinocerebral disease, but it has not been studied rigorously and cannot be routinely recommended. In refractory neutropenic patients, granulocyte transfusion may be beneficial until granulocyte recovery (Chapter 153). Instituting deferasirox or substituting it for other iron chelation agents does not appear to be beneficial.

PROGNOSIS

Because the first-line antifungal typically used for aspergillosis is voriconazole, which lacks activity against Mucorales, failure to achieve a timely diagnosis of pulmonary mucormycosis and delayed antifungal therapy is associated with rapidly worsened outcome. However, the prognosis of mucormycosis appears to be improving with earlier diagnosis and better treatment. Isolated sinusitis is curable by following timely surgical intervention and systemic antifungal therapy. In one review of 929 documented cases of mucormycosis, the mortality rate was 62% in rhinocerebral mucormycosis, 24% in sino-orbital involvement, and 16% in isolated sinus disease. Mortality also remains over 50% in pulmonary mucormycosis.[22] Primary gastrointestinal mucormycosis is associated with an 85% mortality rate.

PNEUMOCYSTIS PNEUMONIA

JOSEPH A. KOVACS

DEFINITION

Pneumocystis jirovecii is a fungus that causes pneumonia almost exclusively in immunodeficient patients. *Pneumocystis* pneumonia (PCP) has been the most common life-threatening opportunistic infection in persons infected with human immunodeficiency virus (HIV), especially those with acquired immunodeficiency syndrome (AIDS). Although the frequency of PCP has decreased in HIV-infected patients, first in association with the widespread use of anti-*Pneumocystis* prophylaxis and later with the introduction of effective combination antiretroviral therapy for HIV/AIDS, it continues to be seen commonly in HIV-infected and other immunodeficient patients.[1] The risk of PCP has been increasing among renal transplant recipients, especially in Europe and Australia.

The Pathogen

Pneumocystis is an ascomycete fungus of the subphylum Taphrinomycotina, most closely related to *Schizosaccharomyces*, *Taphrina*, and *Saitoella* species of fungi. Molecular studies, including whole-genome sequencing, demonstrate that the genus *Pneumocystis* includes a group of closely related organisms that are unique species, each of which can likely infect only a single host species. The organisms previously called *Pneumocystis carinii* are reserved for a species that infects rats, whereas the organism infecting humans is named *P. jirovecii*. Despite the name change, PCP (for *Pneumocystis* pneumonia) remains the preferred acronym for human disease.

Pneumocystis species show a fairly strict host specificity: attempts to transmit, for example, rat or human *Pneumocystis* to mice have been unsuccessful. Molecular evolutionary studies suggest that *Pneumocystis* species coevolved with their hosts, with host jumps rarely occurring. *Pneumocystis* does not

PNEUMOCYSTIS PNEUMONIA

JOSEPH A. KOVACS

DEFINITION

Pneumocystis jirovecii is a fungus that causes pneumonia almost exclusively in immunodeficient patients. *Pneumocystis* pneumonia (PCP) has been the most common life-threatening opportunistic infection in persons infected with human immunodeficiency virus (HIV), especially those with acquired immunodeficiency syndrome (AIDS). Although the frequency of PCP has decreased in HIV-infected patients, first in association with the widespread use of anti-*Pneumocystis* prophylaxis and later with the introduction of effective combination antiretroviral therapy for HIV/AIDS, it continues to be seen commonly in HIV-infected and other immunodeficient patients.[1] The risk of PCP has been increasing among renal transplant recipients, especially in Europe and Australia.

The Pathogen

Pneumocystis is an ascomycete fungus of the subphylum Taphrinomycotina, most closely related to *Schizosaccharomyces*, *Taphrina*, and *Saitoella* species of fungi. Molecular studies, including whole-genome sequencing, demonstrate that the genus *Pneumocystis* includes a group of closely related organisms that are unique species, each of which can likely infect only a single host species. The organisms previously called *Pneumocystis carinii* are reserved for a species that infects rats, whereas the organism infecting humans is named *P. jirovecii*. Despite the name change, PCP (for *Pneumocystis* pneumonia) remains the preferred acronym for human disease.

Pneumocystis species show a fairly strict host specificity: attempts to transmit, for example, rat or human *Pneumocystis* to mice have been unsuccessful. Molecular evolutionary studies suggest that *Pneumocystis* species coevolved with their hosts, with host jumps rarely occurring. *Pneumocystis* does not

ABSTRACT

Pneumocystis jirovecii is a fungus that causes pneumonia (PCP) almost exclusively in immunodeficient patients, especially patients with HIV infection, renal transplant recipients, and patients receiving intensive immunosuppressive regimens for cancer or inflammatory diseases. Patients with PCP typically present with fever, a nonproductive cough, and progressive shortness of breath. Although chest radiographs may be normal early in the disease process, they will often show bilateral interstitial infiltrates that progress to a diffuse alveolar pattern if untreated. Because *Pneumocystis* cannot be cultured, diagnosis is based on detection of the organism by colorimetric or immunofluorescent stains or by polymerase chain reaction (PCR) testing, in respiratory samples, especially bronchoalveolar lavage fluid and induced sputum. Trimethoprim-sulfamethoxazole is the treatment of choice for PCP. Alternatives include dapsone plus trimethoprim, clindamycin plus primaquine, atovaquone, and pentamidine. Adjunctive corticosteroids improve survival in HIV-infected patients with hypoxia ($Pao_2 < 70$ mm Hg). Anti-*Pneumocystis* prophylaxis is effective in preventing PCP in patients at high risk, including HIV-infected patients with CD4 counts less than 200 cells/μL in the absence of combination antiretroviral therapy. Effective prophylactic regimens include trimethoprim-sulfamethoxazole (the first-line agent), dapsone alone or combined with pyrimethamine plus leucovorin, atovaquone, and aerosol pentamidine administered by nebulizer.

grow in culture for a sustained period, so its life cycle is unknown. The two easily recognized forms of the organism are trophic forms (about 2 to 6 µm in diameter) and cysts (also called asci; about 5 to 8 µm in diameter), which can contain up to eight intracystic bodies (ascospores); additional intermediate forms are also seen. Trophic forms, which have an amorphous shape, are estimated to outnumber cysts, which are spherical, by approximately 10:1 in an infected lung.

The genome of *P. jirovecii*, approximately 8.2 million base pairs, is markedly contracted compared with other fungi and has lost multiple metabolic pathways, including enzymes needed to synthesize all amino acids de novo, enzymes needed for chitin synthesis and degradation, and carbonic anhydrase, an enzyme important for regulation of intracellular pH.[2] These findings suggest that *Pneumocystis* lives exclusively in the mammalian host and cannot survive in the external environment other than for the brief periods of time needed to transmit infection to another host.

EPIDEMIOLOGY

Pneumocystis has a worldwide distribution based on serologic studies that show a high prevalence of anti-*Pneumocystis* antibodies in all studied populations. In America and Europe, serologic studies show that most humans develop antibodies to *Pneumocystis* by an early age, thereby suggesting that the organism is ubiquitous.

Pneumocystis is transmitted by the respiratory route, and cysts are required for transmission. There is no evidence that water or fomites play a role in transmission. Data also suggest that transmission can occur transplacentally.

Given its strict host specificity, the source of human infection is presumably other humans, as suggested by occasional outbreaks of a single genotype, especially in recipients of renal transplants.[3] Since clinically apparent PCP is rare and nearly all healthy humans are infected at a young age, *Pneumocystis* infection is also likely acquired from apparently healthy humans, in whom subclinical infection (either asymptomatic or minimally symptomatic) must be quite common.

Molecular genotyping has shown that clinical PCP is often caused by newly acquired strains; whether reactivation of latent infection that was acquired at an early age also contributes to development of pneumonia is unknown. In patients who develop recurrent PCP, however, the recurrence can be due to relapse, especially for early recurrences, or to reinfection with a novel strain.

In immunocompetent hosts, *Pneumocystis* does not appear to cause significant disease. Clinically significant PCP occurs almost exclusively in patients with severe levels of immunodeficiency that are usually associated with a high risk for other opportunistic pathogens: individuals with congenital immunodeficiencies (Chapter 231), especially severe combined immunodeficiency (SCID), hyper–immunoglobulin M (IgM) syndrome, and, to a lesser extent, interleukin-21 (IL-21) receptor deficiency; patients with HIV infection (Chapter 354) and human T-lymphotropic virus-1–associated lymphoma (Chapter 171); patients receiving chemotherapy for the treatment of malignancies, especially lymphoma; transplant patients receiving immunosuppressive therapy; and patients being treated with prolonged courses of immunosuppressive drugs (Chapter 28), especially corticosteroids. In non-HIV patients, up to 90% of patients may be receiving corticosteroid therapy, and higher dose and longer duration increase the risk. Not all patients who receive corticosteroids are at risk, however; for instance, asthmatic patients receiving corticosteroid therapy are at low risk. Biologic agents (Chapter 29), such as alemtuzumab, rituximab, and agents targeting tumor necrosis factor-α (TNF-α), are also associated with an increased absolute risk for PCP, as are idelalisib, ibrutinib, gemcitabine, and iguratimod.[4]

Risk factors for non–HIV-infected patients include underlying disease, older age, use of immunosuppressive drugs, radiation therapy, graft-versus-host disease, graft rejection, and concomitant cytomegalovirus infection (Chapter 347). Patients with malignancies, especially hematologic malignancies but increasingly solid tumors as well, are at risk for PCP primarily owing to the therapies they receive; the incidence can range from 1 to 43% in the absence of prophylaxis and is highly dependent on the intensity and duration of immunosuppression. The incidence of PCP in patients who are receiving chemotherapy for acute myeloid leukemia may be as high as 6 to 7%.[5] In the absence of prophylaxis, the risk for developing PCP in transplant patients, whether hematopoietic stem cell transplantation (Chapter 163) or solid organ transplantation (Chapter 38), is reportedly about 5 to 15%, although lung and heart-lung transplant patients appear to have a higher incidence (up to 43%). Among patients who have a collagen vascular disease, the reported risk is less than 2% without prophylaxis, although patients who have granulomatosis with polyangiitis (Chapter 249) reportedly have a risk of up to 12%. In patients with inflammatory bowel disease (Chapter 127), the incidence is about 1% per year, with a greater risk for Crohn disease compared with ulcerative colitis. PCP also can occur together with coronavirus disease 2019 (COVID-19) infection (Chapter 336) or during the recovery phase, in part probably related to the use of corticosteroids to treat COVID-19.

Among patients with HIV infection, patients with CD4 counts less than 200 cells/µL, and especially those with CD4 counts less than 100 cells/µL, are at greatest risk. Patients with a prior history of PCP and those with unexplained fever, weight loss, or thrush are also at increased risk. Among non-HIV patients, CD4 counts less than 200 cells/µL also appear to increase risk.

PATHOBIOLOGY

Exposure for as little as 1 day to a *Pneumocystis*-infected animal results in transmission of infection. *Pneumocystis* has evolved mechanisms to avoid host initial innate and adaptive immune responses, presumably to facilitate the establishment of primary infection and reinfection in immunocompetent hosts. β-Glucans are masked by surface proteins, and enzymes needed to synthesize outer chain mannans have been lost; both can be recognized by host pattern recognition receptors. The most abundant surface protein of *Pneumocystis*, the major surface glycoprotein, is found on both cysts and trophic forms and is encoded by a multicopy gene family, only one of which is apparently expressed in a given organism; this provides *Pneumocystis* with the potential for antigenic variability. Although more than one *Pneumocystis* species can infect a single animal host species (e.g., rats, dogs), to date only a single *Pneumocystis* species has been found to infects humans; however, molecular typing techniques have demonstrated a high level of diversity among human *Pneumocystis* isolates.

In animal models, an adaptive immune response, which develops against primary infection by approximately 5 to 6 weeks, leads to control and clearance before the burden of organisms produces symptoms. CD4 cells are critical to this control, although B cells and macrophages also are important; B cells appear to have a major role in antigen presentation. CD8 cells can contribute to the associated inflammation. In immunodeficient animal models, the inability to control *Pneumocystis* replication leads to severe pneumonia by 2 to 3 months.

Host inflammatory responses, in part attributable to organism-derived β-glucans, appear to play a critical role in the development of pulmonary symptoms. This relationship may explain why symptoms of PCP develop in patients in whom corticosteroids are being tapered, as well as why the exacerbations of hypoxia can develop approximately 4 days after the initiation of anti-*Pneumocystis* therapy in the absence of concomitant corticosteroid therapy.

Lung pathology in patients with PCP demonstrates an acellular, foamy, eosinophilic, intra-alveolar exudate associated with mild interstitial inflammation (E-Fig. 313-1). This exudate is composed almost entirely of *Pneumocystis* organisms. With progressive disease, hyaline membranes form, and interstitial and intraluminal fibrosis develops. Atypical pathology, including noncaseating granulomas and intrapulmonary cystic changes, can also be seen.

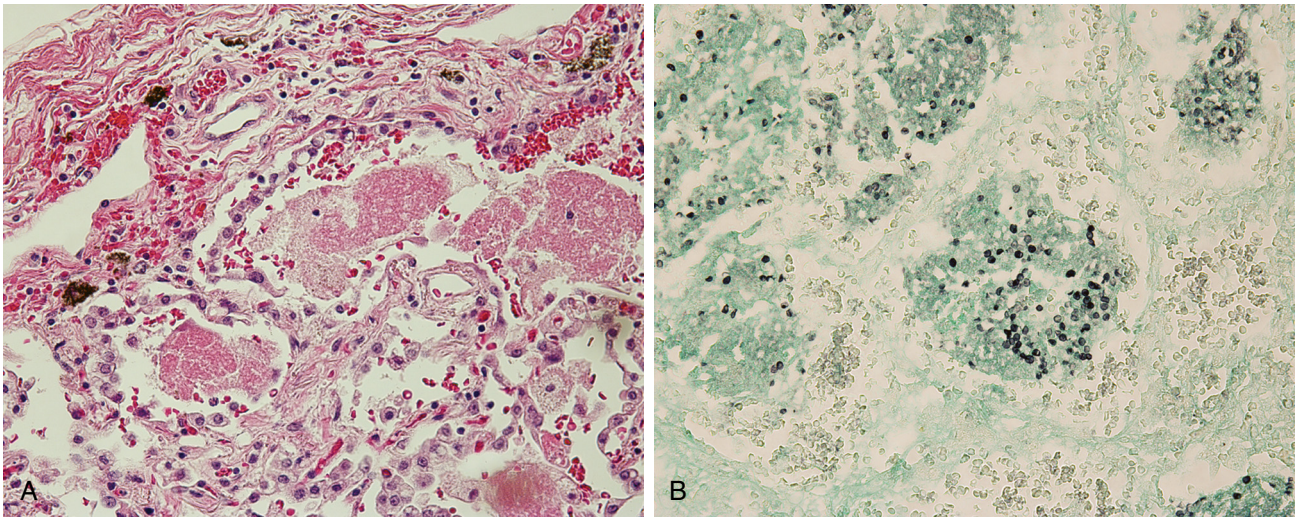
In addition to the previously noted congenital immunodeficiencies and acquired immunosuppression, rare dominant negative allelic variants in the transcription factor Ikaros also appear to confer a very high risk of PCP. Among HIV-infected patients, polymorphisms in the genes for FcγRIIa, IL-4, and the chemokine receptor gene for CCRL2 also have been associated with an increased risk.

Although *Pneumocystis* cannot be cultured, molecular studies have identified mutations in genes that are the targets of anti-*Pneumocystis* therapy, and these mutations may represent the development of resistance by *Pneumocystis* to these agents. Mutations in the DHPS gene of *Pneumocystis*, which is the target of sulfamethoxazole and dapsone, occur more frequently in patients who are receiving trimethoprim-sulfamethoxazole or dapsone for prophylaxis.

CLINICAL MANIFESTATIONS

In immunocompetent humans, no well-defined clinical syndrome is associated with *Pneumocystis* infection, although clinically significant pneumonia rarely has been reported in adults. *Pneumocystis* also has been detected by polymerase chain reaction (PCR) testing in patients with chronic obstructive pulmonary disease (COPD; Chapter 76), but it has not been associated with a worsening clinical course.

In immunosuppressed patients, pneumonia is the primary clinical manifestation of *Pneumocystis* infection. PCP typically presents with a fever, nonproductive cough, and shortness of breath[6] that initially occurs only on exertion but, without therapy, inevitably progresses to dyspnea at rest. Symptoms may be insidious, developing over the course of a few weeks, as is common in patients with HIV infection,[7] or over the course of only a few days, as is more common in non-AIDS patients. Purulent sputum production is unusual, and chills and chest pain occur in a minority of patients. Patients



E-FIGURE 313-1. **Histopathology of the lung of a patient who died from *Pneumocystis* pneumonia (PCP). A,** The hematoxylin and eosin–stained section shows the characteristic acellular, eosinophilic, intra-alveolar exudate that is typical of PCP. **B,** Methenamine silver staining of lung tissue from the same patient demonstrates black-staining cysts scattered throughout the intra-alveolar exudates.

with HIV infection may present with other manifestations of immunodeficiency, including weight loss and thrush. In non-AIDS patients, in whom corticosteroids (Chapter 28) are a common risk factor,[8] clinical manifestations may develop as corticosteroids are being tapered, presumably representing the unmasking of an inflammatory response to the infection as immunosuppression is decreased.

Extrapulmonary disease can rarely involve the skin, eye (choroiditis), central nervous system, bone marrow, thyroid, spleen, liver, gastrointestinal tract, lymph node, or multiple organs in disseminated disease (E-Fig. 313-2), with or without concurrent pneumonia. The risk is somewhat higher but still extremely rare in HIV-infected patients who use aerosolized pentamidine for prophylaxis. Symptoms, which are related to the particular involved site, may be nonspecific, and the diagnosis is often made at autopsy.

DIAGNOSIS

PCP can be the initial presentation of HIV infection. Given the nonspecific symptoms, especially early in the disease process, clinicians must have a high index of suspicion for PCP even in patients not known to be immunosuppressed.[9] Knowledge of the most recent CD4 count is helpful in assessing HIV-infected patients because PCP is rare if the CD4 counts are above 200 cells/μL.

Physical examination and routine laboratory tests are nonspecific and usually not helpful in making the diagnosis of PCP. Even though patients may be tachypneic and appear to be in respiratory distress, they may have an entirely normal lung examination early in the disease course. Lymphopenia is common but is a manifestation of the underlying disease rather than PCP. Lactate dehydrogenase (LDH) levels are often elevated but have poor specificity. Serologic tests also are generally not helpful in diagnosing PCP.

The initial evaluation should include a chest radiograph and assessment of arterial oxygenation, either by blood gas measurement or by pulse oximetry. The chest radiograph typically shows perihilar or diffuse bilateral interstitial infiltrates that progress to a diffuse alveolar pattern (Fig. 313-1). However, PCP has been associated with unilateral disease, focal disease, consolidation, nodules, cavities, pneumothorax, and, rarely, pleural effusions. In up to 30% of patients with HIV infection, the chest radiograph appears normal; in this situation, a computed tomography (CT) scan of the chest, especially high-resolution CT, is invariably abnormal and usually shows a patchy or diffuse ground-glass pattern (see Fig. 313-1).[10]

Arterial oxygenation at rest is often abnormal, although in 30% or more of cases it is within normal limits. Exercise testing induces desaturation and an increase in the alveolar-arterial oxygen (A-a O_2) gradient in the majority of patients with PCP, even those with normal oxygenation at rest or a normal chest radiograph. An abnormal resting diffusing capacity is also common.

Because *Pneumocystis* cannot be cultured, a definitive diagnosis of PCP requires detection of the organism in a respiratory sample.[11] Although expectorated sputum has a low diagnostic yield, induced sputum, combined with immunofluorescent staining (Fig. 313-2)[12] specific for *Pneumocystis*, can be performed and interpreted rapidly and can have a sensitivity approaching 90%. In many centers, however, the diagnostic yield is much lower, likely due in part to variability in the methods used for induction and processing. Ideally, sputum induction should be the first step in diagnosis, followed by bronchoscopy with bronchoalveolar lavage (Fig. 313-3). Bronchoscopic or open lung biopsy is rarely needed to make the diagnosis.

PCR-based assays are 10- to 100-fold more sensitive than stains for detecting *Pneumocystis* and can detect the organism in expectorated sputum, nasopharyngeal aspirates, oropharyngeal wash samples, whole blood samples, and cell-free DNA from serum or plasma,[13] which have a lower organism burden than induced sputum or bronchoalveolar lavage (BAL) samples.[14] This increased sensitivity, however, is associated with decreased specificity because of detection of colonization or subclinical infection that does not require specific anti-*Pneumocystis* therapy. Quantitative PCR assays may help distinguish colonization from clinically significant infection.

The differential diagnosis of pulmonary infiltrates in immunosuppressed patients is very broad and includes infections such as COVID-19 (Chapter 336), adenovirus (Chapter 333), cytomegalovirus (Chapter 347), tuberculosis (Chapter 299), cryptococcosis (Chapter 309), histoplasmosis (Chapter 308), aspergillosis (Chapter 311), and toxoplasmosis (Chapter 320), as well as noninfectious processes such as tumor, heart failure (Chapter 45), pulmonary emboli (Chapter 68), radiation- and chemotherapy-induced pneumonitis, and, especially in HIV-infected patients (Chapter 359), nonspecific interstitial pneumonitis and Kaposi sarcoma.

TREATMENT

Specific anti-*Pneumocystis* therapy should be initiated promptly when the diagnosis is suspected in a potentially susceptible patient. The diagnosis must be definitively confirmed as soon as possible so as to avoid delaying therapy for another process, but delaying such confirmation for a few days after the initiation of therapy will not decrease the diagnostic yield because organisms can be detected in clinical samples for more than 3 weeks after the initiation of therapy.

The treatment of choice for PCP or extrapulmonary *Pneumocystis* disease is trimethoprim-sulfamethoxazole (Table 313-1). HIV-infected patients should be treated for 21 days and non-HIV patients for at least 14 days.[15] Observational data suggest the lower doses (<10 mg/kg/day of trimethoprim and <50 mg/kg/day of sulfamethoxazole) may be as efficacious as higher doses and better tolerated.[16]

Oral therapy should be reserved for patients with mild to moderate disease in whom poor absorption is not a concern. Outpatient therapy should be reserved for patients with mild to moderate disease who will reliably return for follow-up.

The major toxicities associated with trimethoprim-sulfamethoxazole include fever, rash, neutropenia, thrombocytopenia, nausea, vomiting, and transaminase elevations. Hyperkalemia and crystalluria have also been reported, and hyponatremia is seen primarily in association with intravenous administration. Toxicities, which usually appear after the first week of therapy, are much more common in HIV-infected patients, in whom they occur in about 50 to 60% of cases; 15 to 35% of these patients discontinue therapy because of the adverse events.

Alternative Antimicrobials for Mild to Moderate PCP

For patients with mild to moderate disease, alternative regimens include trimethoprim-dapsone and clindamycin-primaquine, both of which have response rates (about 90%) and dose-limiting toxicity rates (about 30%) that are similar to trimethoprim-sulfamethoxazole.[17] Adverse reactions to trimethoprim-dapsone include rash, fever, nausea and vomiting, transaminase elevations, methemoglobinemia, anemia, and mild hyperkalemia. Approximately 20 to 30% of patients with adverse reactions to trimethoprim-sulfamethoxazole experience adverse reactions to trimethoprim-dapsone. Toxicities associated with clindamycin-primaquine include fever, rash, diarrhea, anemia, neutropenia, elevations in liver aminotransferase levels, and methemoglobinemia (Chapter 144). For both dapsone and primaquine and, to a lesser extent, sulfamethoxazole, glucose-6-phosphate dehydrogenase deficiency (Chapter 147) can increase the risk for hemolytic anemia and methemoglobinemia.

Another alternative is atovaquone suspension, which should be taken with food to increase its bioavailability and should be avoided in patients with potentially decreased gastrointestinal absorption (e.g., diarrhea). Efavirenz can decrease plasma concentrations of atovaquone. Toxicities of atovaquone include rash, fever, nausea, vomiting, diarrhea, neutropenia, elevations in liver aminotransferase levels, and anemia.

Alternative Antimicrobials for Severe PCP

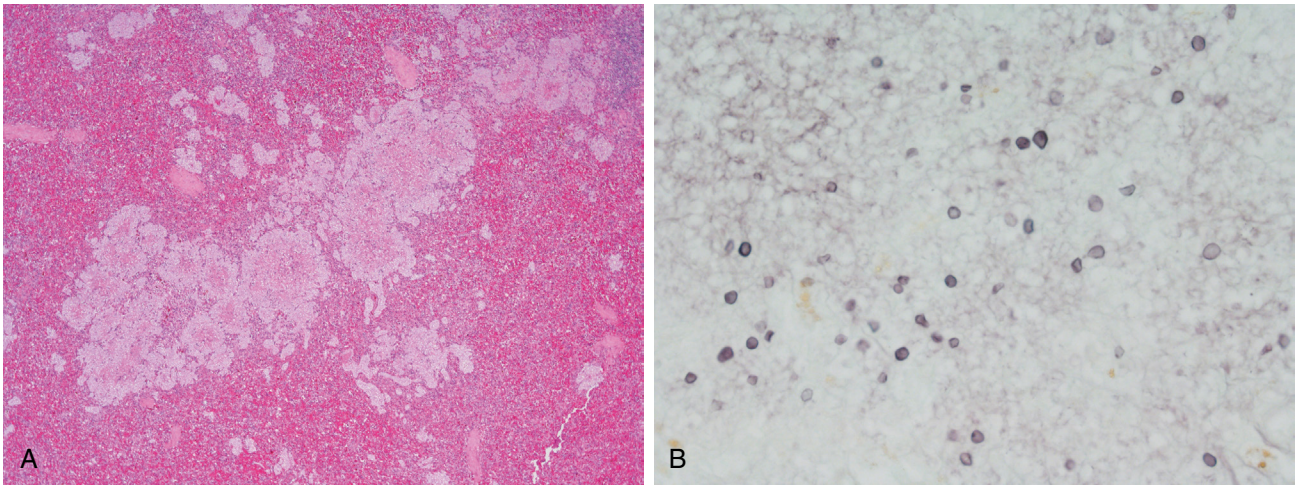
Therapeutic alternatives to trimethoprim-sulfamethoxazole for patients with disease requiring parenteral therapy are limited to clindamycin-primaquine (but only clindamycin is available for intravenous administration) and pentamidine. Caspofungin should not be used as monotherapy and is of uncertain benefit when added to other agents.[18]

Intravenous pentamidine, which is as efficacious as trimethoprim-sulfamethoxazole, must be given as a slow (>1 hour) infusion. However, toxicities occur in about 50 to 60% of patients treated with pentamidine and frequently result in discontinuation of the drug. These toxicities include hypoglycemia, nephrotoxicity, hyperglycemia, fever, neutropenia, thrombocytopenia, hypotension, hyperkalemia, aminotransferase elevations, and pancreatitis. Hypoglycemia may be life-threatening and may precede the development of hyperglycemia; hyperglycemia may be irreversible. Torsades de pointes (Chapter 53) has also rarely been reported.

Adjunctive Corticosteroid Therapy

In HIV-infected patients with moderate to severe disease (Pao_2 < 70 mm Hg or A-a O_2 gradient > 35 mm Hg), a tapering 21-day regimen of adjunctive corticosteroids (see Table 313-1) is indicated to reduce the likelihood of respiratory failure and mortality by 50%. Adjunctive corticosteroids are not associated with a significant increase in opportunistic complications other than localized herpes simplex infection.[A1] Corticosteroids do not benefit patients with mild disease. They also are not of proven benefit if started more than 72 hours after treatment has begun, although it is reasonable to add them if patients exhibit deterioration after this time.

In non-HIV patients, who are often receiving corticosteroids as part of the treatment regimen for their underlying disease, the optimal dosing of corticosteroids is uncertain. Treatment is usually individualized with expert consultation to balance the immunosuppressive effects that potentially contributed to the development of PCP against the anti-inflammatory effects that may ameliorate life-threatening pulmonary dysfunction.[19] A reasonable current approach is to administer corticosteroids to non-HIV patients with moderate or severe disease if they were not receiving corticosteroids, using the same regimen as for HIV-infected patients; for patients already taking corticosteroids at lower doses, the dosage could be increased (see Table 313-1).



E-FIGURE 313-2. Histopathology of the spleen of a patient who died from disseminated *Pneumocystis* infection. A, The hematoxylin and eosin–stained section of the spleen shows large aggregates of *Pneumocystis* organisms. **B**, Methenamine silver stain demonstrates multiple cysts in the spleen. This patient, who was infected with the human immunodeficiency virus, had multiple prior episodes of *Pneumocystis* pneumonia and, at autopsy, had *Pneumocystis* organisms in multiple organs, including the lungs, endocardium, liver, testes, brain, and dermal capillaries. (Courtesy of David Kleiner, MD, PhD, National Cancer Institute.)

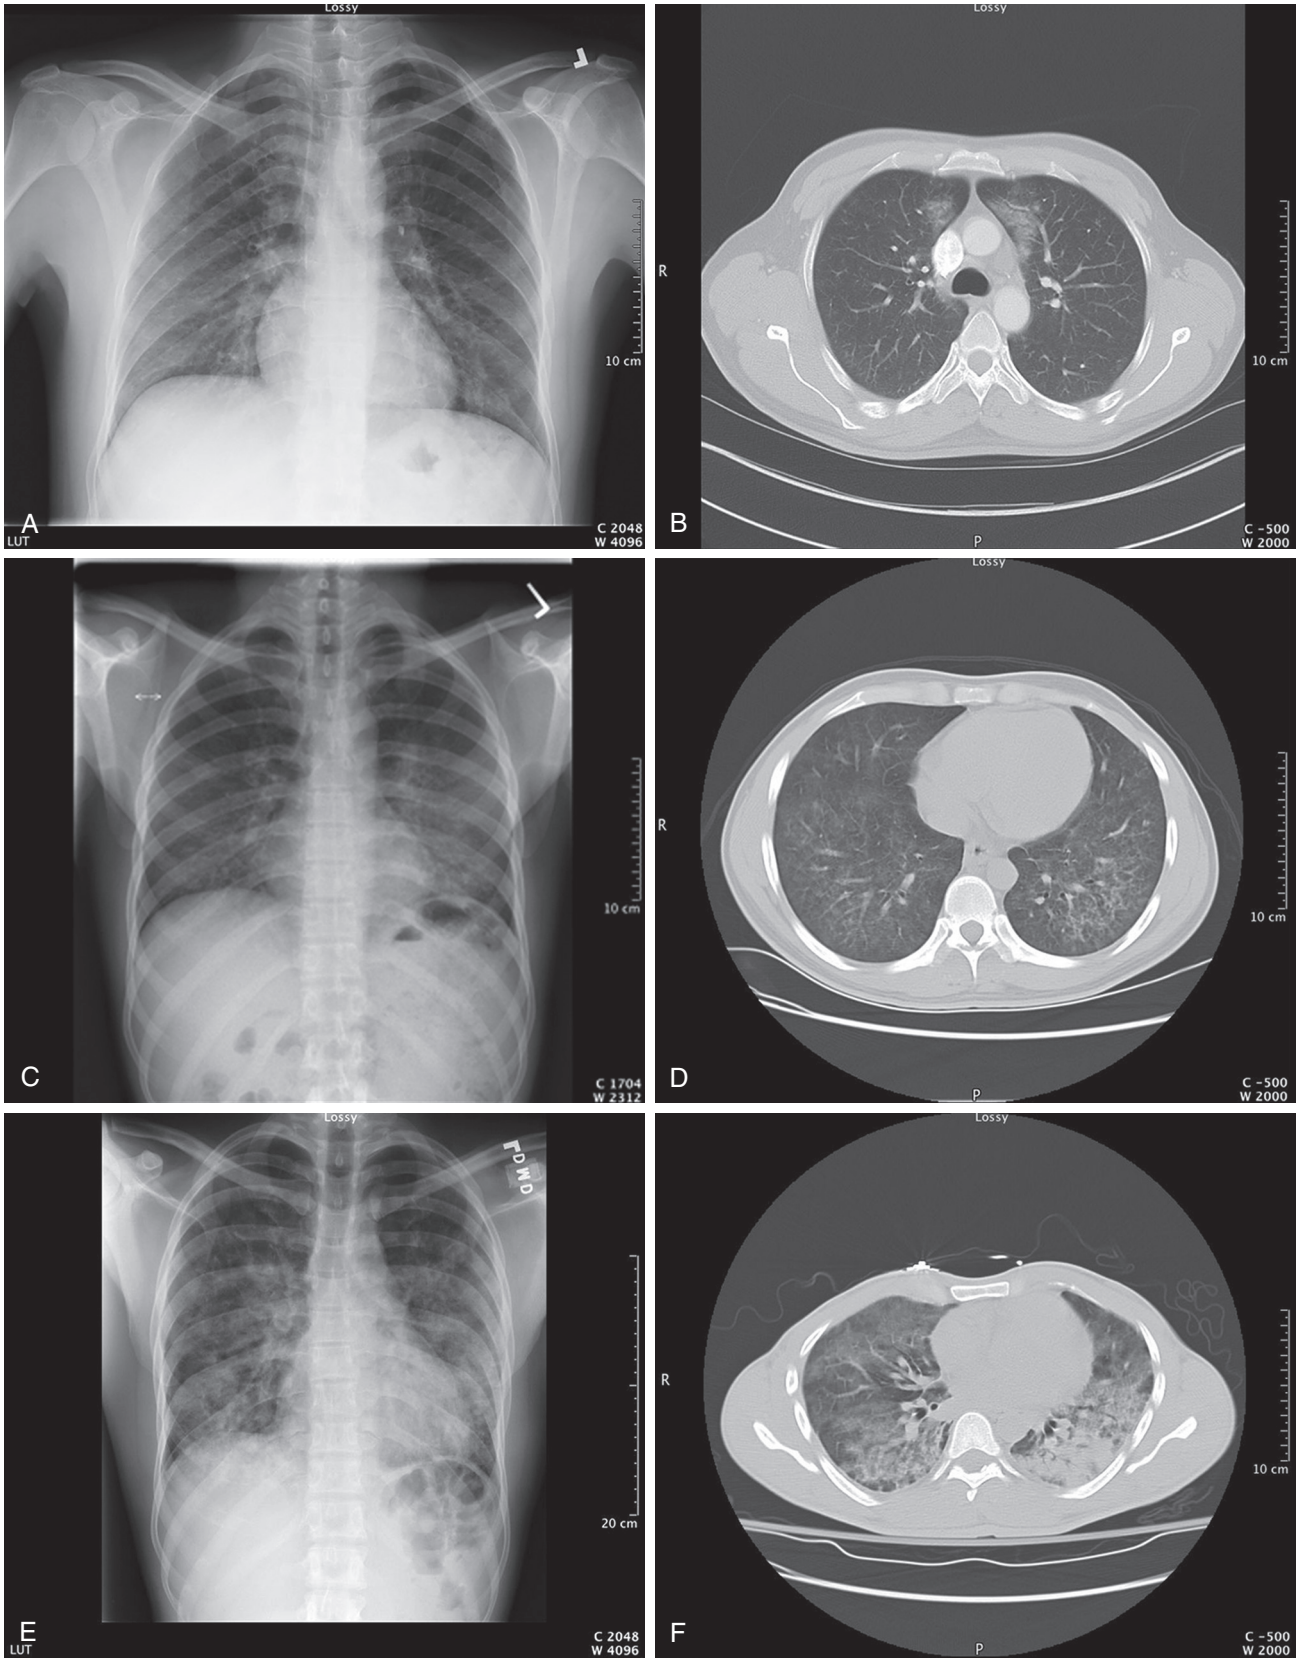


FIGURE 313-1. Chest radiographs (A, C, E) and corresponding computed tomography (CT) scans (B, D, F) from three HIV patients diagnosed with laboratory-confirmed *Pneumocystis* pneumonia. Patient 1 presented with no symptoms; had minimal abnormalities on an incidental chest radiograph (**A**), suggesting an interstitial process; and had focal infiltrates on CT (**B**). Patient 2 presented with fever and weight loss but no shortness of breath. Pulse oximetry demonstrated 99% saturation at rest, with a decrease to 89% with exercise. Chest radiograph (**C**) showed bilateral lower lobe infiltrates, and CT (**D**) showed bilateral lower lobe interstitial infiltrates with patches of ground-glass attenuation. Patient 3 presented with a 2-week history of fever, night sweats, shortness of breath, and weakness. His Pao_2 at diagnosis was 67 mm Hg, and his A-a O_2 gradient was 53 mm Hg. Chest radiograph (**E**) showed bilateral mid and lower lung field infiltrates, and CT (**F**) showed bilateral infiltrates with lower lung consolidation.

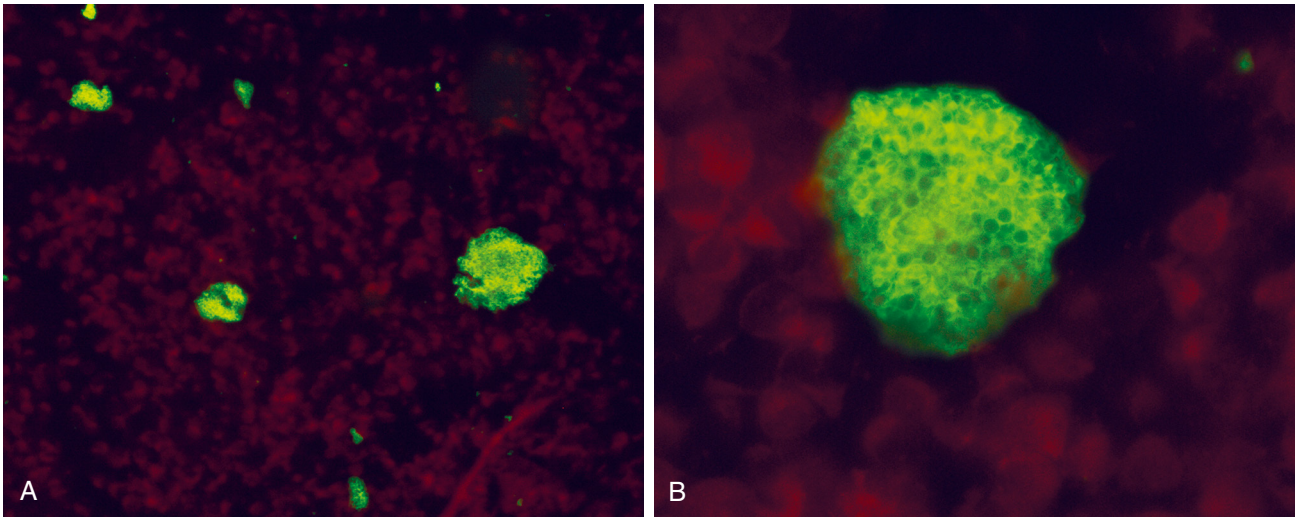

FIGURE 313-2. **Immunofluorescent detection of *Pneumocystis* using a direct fluorescent antibody test to examine an induced sputum sample. A,** Low power (100× original) allows visualization of multiple clusters of organisms staining bright green. **B,** With high power (400× original), individual organisms can be seen within a single cluster.

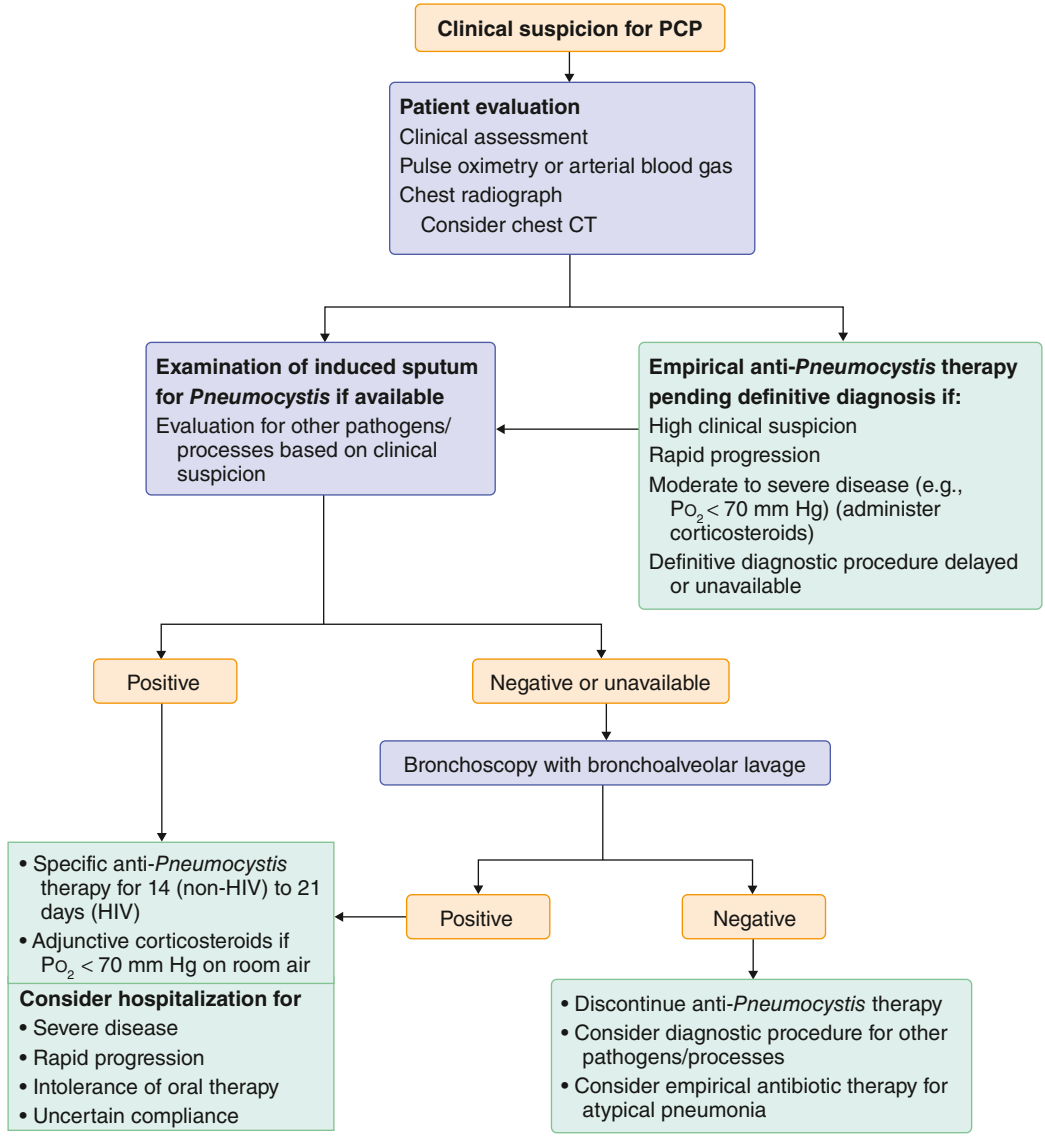

FIGURE 313-3. **Algorithm for the evaluation of patients with suspected *Pneumocystis* pneumonia (PCP).** CT = computed tomography; HIV = human immunodeficiency virus.

TABLE 313-1 DRUG REGIMENS FOR TREATMENT OF PNEUMOCYSTIS PNEUMONIA (PCP)

INDICATION	REGIMEN PREFERENCE	DRUG	ROUTE	DOSE	COMMENTS
Mild PCP: PaO_2 ≥70 mm Hg or A-a O_2 gradient <35 mm Hg	Preferred	Trimethoprim-sulfamethoxazole (TMP-SMX)	PO	2 double-strength (160 TMP + 800 SMX) tablets tid	
	Alternative	Trimethoprim plus	PO	5 mg/kg tid (15 mg/kg/d)	If possible test for G6PD deficiency before use
		Dapsone	PO	100 mg qd	
	Alternative	Clindamycin plus	PO	450 mg qid or 600 mg tid	If possible test for G6PD deficiency before use
		Primaquine	PO	30 mg (base) qd	
	Alternative	Atovaquone	PO	750 mg bid with food	
Moderate to severe PCP: PaO_2 <70 mm Hg or A-a O_2 gradient >35 mm Hg; moderate PCP (A-a O_2 gradient 35 to 45 mm Hg); can be treated with an oral regimen	Preferred	TMP-SMX	IV	5 mg/kg q8h TMP and 25 mg/kg q8h SMX (15 mg/kg/d TMP and 75 mg/kg/d SMX)	May switch to oral therapy following clinical improvement
	Alternative	Pentamidine	IV	3-4 mg/kg qd	Infuse over >60 min
	Alternative	Clindamycin plus	IV	600 mg q6h or 900 mg q8h	May switch to oral therapy following clinical improvement
		Primaquine	PO	30 mg (base) qd	No parenteral formulation is available
Adjunctive therapy for moderate to severe PCP: PaO_2 <70 mm Hg or A-a O_2 gradient ≥35 mm Hg	Preferred	Prednisone	PO	40 mg bid, days 1-5; 40 mg qd, days 6-10; 20 mg qd days 11-21	Begin as early as possible and within 72 hr; efficacy if started later has not been demonstrated
	Preferred	Methylprednisolone	IV	30 mg bid, days 1-5; 30 mg qd, days 6-10; 15 mg qd days 11-21	Use if parenteral therapy is necessary

Note: HIV-infected patients should receive 21 days of therapy; non-HIV patients should receive at least 14 days of therapy. Nonrandomized studies have found similar efficacy but better tolerability with lower doses of trimethoprim-sulfamethoxazole (e.g., ≤10 mg/kg/d TMP and 50 mg/kg/d SMX).
Bid = twice daily; G6PD = glucose-6-phosphate dehydrogenase; IV = intravenously; PO = orally; qd = daily; qid = 4 times daily; tid = 3 times daily.

Initiation of Antiretroviral Therapy

Many HIV-infected patients who are diagnosed with PCP are not yet receiving antiretroviral therapy. In general, it is preferable to initiate antiretroviral therapy while patients are being treated for PCP, because such therapy appears to be associated with an improved outcome (Chapter 358).[A2] Major concerns about initiating antiretroviral therapy include the risk for adverse drug reactions, which may be confused with adverse reactions to anti-PCP therapy; the risk for overlapping toxicities, which may complicate management; and the risk for immune reconstitution (Chapters 357 and 358), which has been rarely reported but can be life-threatening. Thus, many clinicians initiate antiretroviral therapy during or immediately after completion of anti-*Pneumocystis* therapy but after the patient has shown clinical improvement and is able to tolerate oral medications. A recurrence of symptoms after starting antiretroviral therapy may be caused by the immune reconstitution syndrome (IRIS; Chapter 358), which may require corticosteroid therapy. Although optimal treatment regimens have not been well-defined, a reasonable initial regimen for severe immune reconstitution inflammatory syndrome is 1 to 2 mg/kg of prednisone or equivalent, with a subsequent taper based on the improvement of symptoms.

Treatment Failure

In patients who have progressive respiratory deterioration despite therapy, it is critical to confirm the diagnosis of PCP, usually by bronchoscopy, to exclude other concurrent processes (e.g., other infections, heart failure, pulmonary emboli). Parenteral therapy should be used to eliminate concerns about drug absorption. Because patients who will ultimately respond can deteriorate for 3 to 4 days, especially in the absence of concomitant corticosteroid therapy, it is reasonable to wait 5 to 8 days before considering a change in drug therapy, other than to add corticosteroids if not already prescribed.

When a change in anti-PCP therapy is indicated because of nonresponse or toxicity, trimethoprim-sulfamethoxazole should be the first choice if the patient has not previously had a life-threatening adverse reaction to it. Rapid desensitization (similar to penicillin desensitization), ideally in consultation with an allergy specialist, can be considered in patients with prior adverse reactions, but patients with a history of Stevens-Johnson syndrome or toxic epidermal necrolysis should not be rechallenged. Clindamycin-primaquine likely is superior to pentamidine in patients who have failed to respond to a first-line regimen.

PREVENTION

Although *Pneumocystis* is transmitted by the airborne route, exposure to the organism appears to be ubiquitous in humans, thereby suggesting that avoidance of exposure may be difficult. Respiratory isolation of patients with active PCP is not required, although recent outbreaks in renal and liver transplant patients strongly suggest that a susceptible patient should not share a room with a PCP patient.

Trimethoprim-sulfamethoxazole is highly effective in preventing *Pneumocystis* infection in a wide range of susceptible populations.

Patients with HIV/AIDS

Primary prophylaxis is indicated in HIV/AIDS patients with CD4 counts below 200 cells/μL in the absence of antiretroviral therapy. Although 10 to 15% of patients who develop PCP have higher CD4 counts, the incidence is very low in such patients. Nevertheless, patients whose CD4 counts are greater than 200 cells/μL but who have a CD4 percentage of less than 14% or a history of an AIDS-defining illness are also candidates for primary prophylaxis. Patients who develop PCP should be placed on secondary prophylaxis after the treatment regimen is successfully completed. When the CD4 count has been above 200 cells/μL for at least 3 months (ideally in the setting of controlled HIV replication), both primary and secondary prophylaxis can be safely discontinued because the risk for developing PCP is no greater than in patients whose CD4 counts never fell below 200 cells/μL. Recent observational studies suggest that prophylaxis can also be safely discontinued in patients who have CD4 counts between 100 and 200 cells/μL and who have virologically suppressed HIV[20]; a reasonable approach is to discontinue prophylaxis in such patients if the viral load remains below detection limits for 3 to 6 months. In patients with CD4 counts less than 100 cells/μL, prophylaxis should be maintained regardless of the viral load.

Non-HIV Patients

Prophylaxis is also recommended for high-risk patients who do not have HIV infection (Table 313-2). Prophylaxis is recommended for allogeneic stem cell transplant recipients (Chapter 163) from the time of engraftment to at least 6 months after transplantation, and longer for patients who continue receiving immunosuppressive therapy or who have chronic graft-versus-host disease. For recipients of autologous stem cell transplants who have a lower risk for PCP, prophylaxis for 3 to 6 months should be considered if the degree of immunosuppression is substantial owing to underlying disease or therapy (e.g., patients with leukemia or lymphoma receiving intensive conditioning or immunosuppressive therapy). Cancer patients meeting the following conditions should receive prophylaxis: acute lymphocytic leukemia, throughout therapy; therapy with alemtuzumab, for 2 months after completion and until CD4 is greater than 200 cells/μL; therapy with idelalisib with or without rituximab, or with prolonged corticosteroids, or temozolomide combined with radiation therapy, at least through active therapy; therapy with purine analogues or other T-cell–depleting regimens, consider until CD4 is greater than 200 cells/μL.[21]

TABLE 313-2 RECOMMENDATIONS FOR ANTI-*PNEUMOCYSTIS* PROPHYLAXIS IN PATIENTS WITHOUT HIV INFECTION

CATEGORY	DISEASE OR DRUG	DURATION OF PROPHYLAXIS
Solid organ transplant recipients	All solid organ transplant recipients	At least 6-12 months post-transplant, with longer duration in certain settings as noted later
	Lung and small bowel transplant recipients	Lifelong
	Heart, liver, and renal transplant recipients	Some experts recommend prolonged, possibly lifelong, depending in part on the level of immunosuppression
	Greater immunosuppression (e.g., for GVHD, rejection)	Prolonged; maintain during periods of increased immunosuppression
	CMV disease	Prolonged
Hematologic malignancies	Acute lymphoblastic leukemia	From induction to end of maintenance
	Adult T-cell leukemia/lymphoma	From diagnosis to end of therapy
	Allogeneic stem cell transplant	For >6 months after engraftment and as long as immunosuppression continues; consider extending after cord blood transplant or when the GVHD prophylaxis involved T-cell depletion
	Autologous stem cell transplant, for recipients with substantial immunosuppression related to an underlying condition or its treatment, including brentuximab vedotin therapy	For 3 to 6 months post-transplant, longer if immunosuppression is continued
	Long-term corticosteroid treatment with >20 mg daily prednisone or the equivalent for >4 weeks	Until corticosteroid dose is reduced to below threshold levels
	Idelalisib	Per package insert, during therapy; consider continuing for 2 to 6 months after discontinuation
	Fludarabine + cyclophosphamide + rituximab therapy	>6 months after completion of treatment
	Alemtuzumab	Per package insert, >2 months after completion of therapy or until the CD4+ count is >200 cells/mL, whichever occurs later; consider continuing for >6 months after completion of therapy
	Temozolomide (in combination with radiotherapy)	Per package insert, during therapy, and until lymphopenia resolves; consider continuing for >6 months after completion of therapy
	Can consider for:	
	R-CHOP14 or escalated BEACOPP	Duration of immunosuppressive therapy
	Purine analogs (e.g., cladribine, fludarabine) or other T-cell–depleting agents	Duration of immunosuppressive therapy; consider continuing until CD4 cell count is >200 cells/μL
	Brain irradiation with high-dose corticosteroids	Duration of immunosuppressive therapy
	CD4 cell count <200 cells/μL	Until CD4 cell count is >200 cells/μL
Inflammatory bowel disease	On triple immunosuppressive therapy, including corticosteroids, methotrexate, thiopurines, and biologics	Duration of immunosuppressive therapy
	Can consider if:	
	On double immunosuppressive therapy, especially if one of these is a calcineurin inhibitor	Duration of immunosuppressive therapy
	For any combination of high-dose corticosteroids, low lymphocyte count, or JAK inhibitors	Duration of immunosuppressive therapy
Rheumatologic diseases	Long-term corticosteroids with >20 mg prednisone daily or the equivalent for >4 weeks, especially when combined with another immunosuppressive agent (e.g., cyclophosphamide)	Duration of immunosuppressive therapy
	Granulomatosis with polyangiitis and eosinophilic granulomatosis with polyangiitis receiving rituximab or cyclophosphamide	Duration of immunosuppressive therapy
Other indications	Prior *Pneumocystis* pneumonia	Until underlying risk factor resolves
	Long-term corticosteroids with >20 mg prednisone daily or the equivalent for >4 weeks in the setting of an underlying inflammatory disease or malignancy	Until corticosteroid dose is reduced to below threshold levels

Note: Criteria for anti-*Pneumocystis* prophylaxis in non-HIV patients and duration of prophylaxis are often not well-defined. Recommendations are based on product inserts, published guidelines, and expert opinion.
BEACOPP = bleomycin, etoposide, doxorubicin hydrochloride (Adriamycin), cyclophosphamide, vincristine (Oncovin), procarbazine, and prednisone; CHOP14 = cyclophosphamide, doxorubicin, vincristine, prednisolone on a 14-day interval; CMV = cytomegalovirus; GVHD = graft-versus-host disease; JAK = Janus kinase.

For solid organ transplant patients, prophylaxis has been used primarily in centers with a known incidence greater than 3%. Guidelines recommend the administration of prophylaxis for 6 to 12 months[22] in most solid organ transplant patients, with lifelong prophylaxis in recipients of lung and intestinal transplants, and consideration of extended prophylaxis in recipients of heart, liver, and renal transplants. If extended therapy is not used, prophylaxis is recommended during periods of increased risk (e.g., recent or concurrent cytomegalovirus infection, increased immunosuppression for graft rejection, higher-dose corticosteroid therapy, and treatment with rituximab or belatacept).[23]

Patients with inflammatory bowel disease (Chapter 127) appear to be at increased risk as newer immunosuppressive agents are used. Consensus-based guidelines recommend prophylaxis for patients who are receiving triple immunomodulator therapy.

Although there are no consensus guidelines on the use of prophylaxis for patients receiving corticosteroids, one reasonable approach is to provide prophylaxis to patients with an underlying immunosuppressive or inflammatory disease who receive at least 20 mg of prednisone or equivalent for longer than 1 month.[24,25] Among non–HIV-infected patients, a CD4 count below 200 cells/μL also appears to increase susceptibility. However, CD4 counts are not routinely measured, and clinical decisions generally are not based on them.

Trimethoprim-sulfamethoxazole, which is the first-line agent for prophylaxis in all populations (Table 313-3), is highly effective.[A3] Limited data from small studies suggest that one half-strength dose per day may be as efficacious and less toxic compared with higher doses.[A4,A5] Alternatives include dapsone alone or combined with pyrimethamine plus leucovorin, atovaquone, and aerosolized pentamidine. Patients who are receiving pyrimethamine, sulfadiazine, and leucovorin to treat toxoplasmosis do not require additional anti-*Pneumocystis* prophylaxis because this regimen also prevents PCP.

HIV-infected patients with a prior history of a mild sulfa allergy (e.g., mild rash, excluding those with prior Stevens-Johnson syndrome or toxic epidermal necrolysis) can often be safely rechallenged with trimethoprim-sulfamethoxazole. Dose escalation over a 6- to 13-day period is associated with better tolerance than direct rechallenge with full-dose trimethoprim-sulfamethoxazole, and up to 75% of patients can continue to receive trimethoprim-sulfamethoxazole for at least 6 months.

PROGNOSIS

Mortality for untreated PCP approaches 100%. With therapy, the survival rate for HIV-infected patients with confirmed PCP is now as high as 95%, but a poorer survival rate of about 75% has been reported in patients without HIV

TABLE 313-3 DRUG REGIMENS FOR PREVENTION OF *PNEUMOCYSTIS* PNEUMONIA (PCP)

INDICATION	DRUG	ROUTE	DOSE	COMMENTS
Preferred	Trimethoprim-sulfamethoxazole (TMP-SMX)	PO	1 double-strength tablet (160 mg TMP + 800 mg SMX) or one single-strength tablet (80 mg TMP + 400 mg SMX) daily	Also active in preventing toxoplasmosis
Alternative	TMP-SMX	PO	1 double-strength tablet (160 mg TMP + 800 mg SMX) three times weekly	Also active in preventing toxoplasmosis
Alternative	Dapsone	PO	100 mg daily or 50 mg twice daily	Test for G6PD deficiency before use
Alternative	Dapsone plus	PO	50 mg daily	Test for G6PD deficiency before use; also active in preventing toxoplasmosis
	Pyrimethamine plus	PO	50 mg once weekly	
	Leucovorin	PO	25 mg once weekly	Should be administered with pyrimethamine to minimize toxicity
Alternative	Atovaquone	PO	1500 mg daily with food	Likely active in preventing toxoplasmosis; efavirenz can decrease concentrations
Alternative	Pentamidine	Aerosol	300 mg via the Respirgard II nebulizer once monthly	Not active in preventing toxoplasmosis
Alternative	Pentamidine	IV	4 mg/kg administered over >1 hr every 4 weeks	Limited observational data primarily in pediatric populations, consider using if no other options; not active in preventing toxoplasmosis

Note: Patients receiving pyrimethamine-sulfadiazine and atovaquone therapy for toxoplasmosis do not appear to need additional prophylaxis for PCP; patients receiving clindamycin-pyrimethamine therapy for toxoplasmosis will need additional prophylaxis for PCP.
G6PD = glucose-6-phosphate dehydrogenase; IV = intravenously; PO = orally.

infection. Risk factors for death in HIV-infected patients include more severe hypoxia, older age, recurrent episodes of PCP, low hemoglobin level, and the presence of comorbid conditions. Higher LDH levels may be associated with increased mortality in both HIV and non-HIV patients.[26] Although mortality for patients admitted to an intensive care unit (ICU) is high, survival for HIV-infected ICU patients now approaches 75%.

314 MYCETOMA AND DEMATIACEOUS FUNGAL INFECTIONS

PETER G. PAPPAS AND DIMITRIOS P. KONTOYIANNIS

DEFINITION

Dematiaceous fungi represent a large group of fungal organisms characterized by the presence of abundant melanin in the cell wall. This melanin gives rise to a brown-black coloration on artificial culture media and in histopathologic specimens. A related term, *phaeohyphomycosis,* refers broadly to infection by these pigmented fungi. The two terms are often used interchangeably. Dematiaceous fungal infections generally fall into three broad categories: mycetoma (e.g., Madura foot), chromomycosis (also known as chromoblastomycosis), and phaeohyphomycosis.[1,2]

The Pathogens

More than 100 dematiaceous fungi have been identified as causes of human disease. The most common organisms and their related conditions are listed in Table 314-1. The taxonomy of the dematiaceous fungi is complicated because these agents belong to different classes, including Hyphomycetes, Ascomycetes, Basidiomycetes, Coelomycetes, and Zygomycetes. The most common agents of phaeohyphomycosis include species in the following genera: *Alternaria, Bipolaris, Curvularia, Exophiala, Cladosporium, Cladophialophora, Fonsecaea, Exserohilum, Verruconis, Phialophora, Phaeoacremonium,* and *Chaetomium*. These agents are ubiquitous saprophytes of soil and decaying matter, and some are important plant pathogens. In tissue, these organisms exist as yeastlike cells, septated hyphae, or a combination of yeast and hyphae. Most of these organisms demonstrate melanin pigmentation (brownish coloration) in the cell walls on microscopic examination.

EPIDEMIOLOGY

Dematiaceous fungi are found in the environment worldwide. Allergic fungal sinusitis associated with dematiaceous fungi appears to be more common in the southern United States. Chronic infections of the lower extremities are more commonly seen in men and in tropical areas. Chromomycoses are more prevalent in rural populations in the tropics and are hyperendemic in certain geographic areas such as Madagascar, India, Brazil, and other poorer countries in Africa and South America. Cutaneous infections usually occur as a result of minor skin trauma and direct inoculation of the organism.

Phaeohyphomycosis is an important emerging fungal infection in medically advanced regions, particularly among immunocompromised patients such as recipients of solid organ[3] and hematopoietic stem cell transplants, patients with prolonged neutropenia, and other immunocompromised individuals. Risk factors for extracutaneous infection include intravenous drug use, chronic sinusitis, freshwater immersion, and chronic immunosuppression. Phaeohyphomycosis is reported in human immunodeficiency virus (HIV)-infected patients but is far less common than other opportunistic fungi. Extracutaneous invasive disease can also occur in otherwise normal patients but is much less common. Subtle host immune abnormalities, including *CARD*-9 mutations and other disorders associated with T_H17 deficiency, have been identified in a subset of these previously "normal" individuals.

Dematiaceous fungal infections can be seen following invasive procedures in health care settings.[4] In the United States, a striking example was an epidemic of fungal meningitis, epidural abscess, sacroiliitis, vertebral osteomyelitis, discitis,

TABLE 313-3 DRUG REGIMENS FOR PREVENTION OF *PNEUMOCYSTIS* PNEUMONIA (PCP)

INDICATION	DRUG	ROUTE	DOSE	COMMENTS
Preferred	Trimethoprim-sulfamethoxazole (TMP-SMX)	PO	1 double-strength tablet (160 mg TMP + 800 mg SMX) or one single-strength tablet (80 mg TMP + 400 mg SMX) daily	Also active in preventing toxoplasmosis
Alternative	TMP-SMX	PO	1 double-strength tablet (160 mg TMP + 800 mg SMX) three times weekly	Also active in preventing toxoplasmosis
Alternative	Dapsone	PO	100 mg daily or 50 mg twice daily	Test for G6PD deficiency before use
Alternative	Dapsone plus	PO	50 mg daily	Test for G6PD deficiency before use; also active in preventing toxoplasmosis
	Pyrimethamine plus	PO	50 mg once weekly	
	Leucovorin	PO	25 mg once weekly	Should be administered with pyrimethamine to minimize toxicity
Alternative	Atovaquone	PO	1500 mg daily with food	Likely active in preventing toxoplasmosis; efavirenz can decrease concentrations
Alternative	Pentamidine	Aerosol	300 mg via the Respirgard II nebulizer once monthly	Not active in preventing toxoplasmosis
Alternative	Pentamidine	IV	4 mg/kg administered over >1 hr every 4 weeks	Limited observational data primarily in pediatric populations, consider using if no other options; not active in preventing toxoplasmosis

Note: Patients receiving pyrimethamine-sulfadiazine and atovaquone therapy for toxoplasmosis do not appear to need additional prophylaxis for PCP; patients receiving clindamycin-pyrimethamine therapy for toxoplasmosis will need additional prophylaxis for PCP.
G6PD = glucose-6-phosphate dehydrogenase; IV = intravenously; PO = orally.

infection. Risk factors for death in HIV-infected patients include more severe hypoxia, older age, recurrent episodes of PCP, low hemoglobin level, and the presence of comorbid conditions. Higher LDH levels may be associated with increased mortality in both HIV and non-HIV patients.[26] Although mortality for patients admitted to an intensive care unit (ICU) is high, survival for HIV-infected ICU patients now approaches 75%.

Phaeohyphomycosis is reported in human immunodeficiency virus (HIV)-infected patients but is far less common than other opportunistic fungi. Extracutaneous invasive disease can also occur in otherwise normal patients but is much less common. Subtle host immune abnormalities, including *CARD*-9 mutations and other disorders associated with T_H17 deficiency, have been identified in a subset of these previously "normal" individuals.

Dematiaceous fungal infections can be seen following invasive procedures in health care settings.[4] In the United States, a striking example was an epidemic of fungal meningitis, epidural abscess, sacroiliitis, vertebral osteomyelitis, discitis,

ABSTRACT

Mycetoma and dematiaceous fungal infections are caused by over 100 fungal species that have the characteristic of being "melanized" or pigmented, thereby leading to a brown or darkish pigmentation in histopathologic samples and in culture. These organisms cause a range of disorders that vary from benign conditions such as onychomycosis, to extremely destructive and disfiguring mycetoma, to life-threatening, invasive infection in an immunocompromised individual. Diagnosis is based on the identity of characteristic fungi on pathologic specimens and is confirmed by culture. The triazole antifungals (e.g., itraconazole, voriconazole, and posaconazole) have the best in vitro and clinical activity versus these pathogens. A combined medical/surgical approach is preferred for patients with mycetoma and extensive tissue involvement and for patients with disseminated phaeohyphomycosis, especially if their central nervous system is involved.

and peripheral arthritis that involved over 750 persons and was caused by *Exserohilum rostratum* following injection of contaminated methylprednisolone acetate from a single compounding pharmacy. Previous reports of infection caused by *Exophiala* species following contaminated steroid injections, infected breast implants, other prosthetic materials, and, rarely, contaminated intravascular catheters and intravenous fluids underscore the importance of these organisms as potential health care–associated pathogens.

Mycetoma has a global distribution (E-Fig. 314-1), but it occurs primarily in the tropical zones. The disorder is quite prevalent in India, Latin America, the Middle East, and sub-Saharan Africa (the "mycetoma belt").[5] Sudan has a particularly high burden of mycetoma. Indigenously acquired mycetoma is sporadic in North America and Europe. The relative frequency of actinomycetoma and eumycetoma differs among geographic areas. Eumycetoma is more common in India and Africa, whereas actinomycetoma is more common in Central and South America. The causative agents of mycetoma differ in their geographic distribution. For example, *Scedosporium apiospermum* is the most common agent of mycetoma in North America, and *Actinomadura* and *Nocardia* species are predominant in Central and South America. *Leptosphaeria senegalensis* and *Madurella mycetomatis* are predominant in sub-Saharan Africa and India.

The ratio of male to female patients with mycetoma is 5 : 1. The disease is typically seen in rural areas and in persons susceptible to local trauma and contamination from soil. Hence, farmers, gardeners, woodcutters, herders, and people who work outside while barefoot are more susceptible to this infection.

PATHOBIOLOGY

Most cases of chromomycosis are caused by three species: *Fonsecaea pedrosoi, Cladosporium carrionii*, and *Phialophora verrucosa*. The distinctive histologic appearance is characterized by the presence of thick-walled, dark brown bodies known as *sclerotic cells* or *copper pennies*, which represent individual organisms and may be seen in clusters or as single cells. The etiologic fungi causing chromomycosis are indistinguishable on histologic examination of tissue.

TABLE 314-1 DEMATIACEOUS FUNGI AND ASSOCIATED DISEASES

CLINICAL CONDITION	COMMON ETIOLOGIC AGENTS
Chromomycosis	*Fonsecaea pedrosoi* *Cladophialophora carrionii* *Phialophora verrucosa*
Cutaneous or subcutaneous disease	*Exophiala jeanselmei* *Exophiala dermatitidis* *Phialophora* spp *Bipolaris* spp *Alternaria* spp
Sinusitis	*Bipolaris* spp *Curvularia* spp *Exserohilum* spp *Alternaria* spp
Central nervous system	*Cladophialophora bantiana* *Verruconis gallopava* *Rhinocladiella mackenziei* *Chaetomium atrobrunneum* *Exophiala dermatitidis*
Health care associated	*Exserohilum rostratum* *Exophiala* spp
Disseminated	*Exophiala dermatitidis* *Exophiala jeanselmei* *Bipolaris* spp *Verruconis gallopava* *Phialophora* spp *Lomentospora prolificans*
Eumycetoma	*Madurella mycetomatis* *Exophiala* spp *Curvularia* spp *Leptosphaeria senegalensis*
Non-dematiaceous fungi	*Scedosporium apiospermum* *Acremonium* spp *Fusarium* spp

spp = species.

Mycetoma is caused by two groups of organisms: (1) the filamentous aerobic actinomycetes (actinomycetoma) and (2) a wide range of saprophytic soil and woody plant fungi (eumycetoma). Eumycetoma accounts for about 50% of cases of mycetoma.[6] A variety of *Nocardia* (Chapter 306) species (e.g., *Nocardia brasiliensis, Nocardia asteroides*), *Actinomadura* species (e.g., *Actinomadura pelletieri, Actinomadura madurae*), and *Streptomyces* species (e.g., *Streptomyces somaliensis*) cause actinomycetoma. Most cases of eumycetoma are due to *Madurella* species (e.g., *Madurella mycetomatis* causes 70% of all cases of eumycetoma worldwide). Other causes of eumycetoma include some nondematiaceous fungi such as *Fusarium* species, *Acremonium* species, *Scedosporium apiospermum,* and several phaeohyphomycetes, including *Exophiala* and *Curvularia* species. Eumycetoma is further characterized on the basis of the color of the granular drainage: white- to yellow-grain mycetomas (white piedra) are typically caused by hyalohyphomycetes (e.g., *S. apiospermum, Fusarium* species, *Acremonium* species), and black-grain eumycetomas are caused by *Madurella* species and other less common fungi.

Local trauma (e.g., wood splinters), introduces a mycetoma-causative organism into the skin and subcutaneous tissues, initiates a chain of events that leads to chronic, suppurative granulomatous inflammation, tumefaction, formation of multiple fistulous tracts and sinuses, deep abscesses, fibrosis, and scar formation. Infection can extend to adjacent connective tissue across the lines of least resistance (fascia) and ultimately to bones, muscles, nerves, and tendon sheaths, thereby leading to gross anatomic distortion of the affected site.

The genetics and immunopathogenesis of mycetoma are not well defined, but it appears that there are differences in host susceptibility as some infected persons have impaired or delayed hypersensitivity reactions or polymorphisms in genes encoding for chemokines (e.g., CCL50) and cytokines (e.g., interleukin-10). Mycetoma does not appear to be more common in immunocompromised hosts.

CLINICAL MANIFESTATIONS

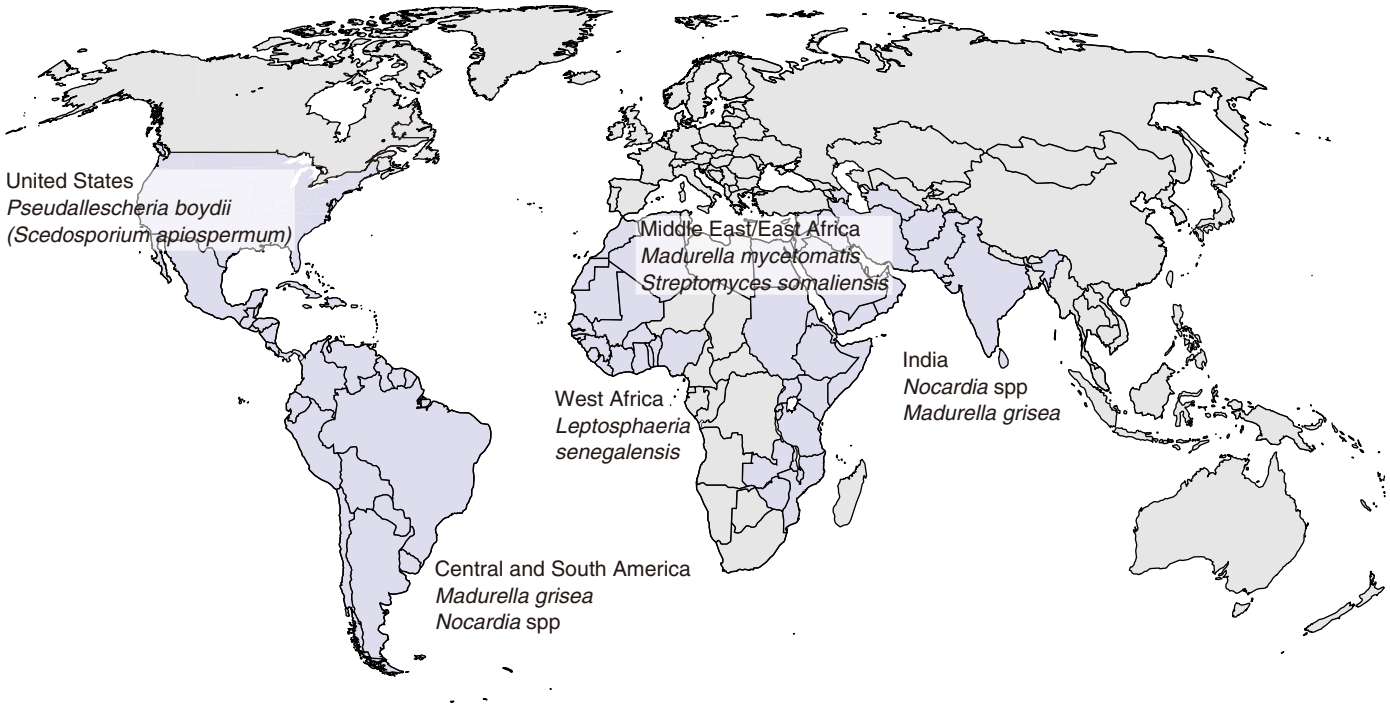
Chromomycosis

Chromomycosis is manifested as a cutaneous or subcutaneous lesion that may range in size from a small papule to a large confluent plaque involving a major portion of an extremity (Fig. 314-1). Single or multiple lesions are seen; ulceration may occur. Lesions may remain unchanged in size and consistency for months or years, although most tend to progress in the absence of specific therapy. Chronic lesions may become dry and crusted with a raised border, which may be smooth or irregular, and which may take on a verrucous, warty appearance. Multiple lesions can coalesce to form larger plaques in which central scarring may develop. Cutaneous lesions usually remain confined to one anatomic site, although nodular lymphangitis and multifocal cutaneous disease from autoinoculation may occur. Common complications include local disfigurement due to scarring and extensive tissue involvement. Disseminated disease involving visceral organs is rare.

Phaeohyphomycosis

Superficial phaeohyphomycosis is characterized by tinea nigra and black piedra. Tinea nigra is a darkening of the skin caused by growth of *Phaeoannellomyces*

FIGURE 314-1. A 42-year-old renal transplant recipient with lower extremity chromomycosis due to *Fonsecaea pedrosoi*.



E-FIGURE 314-1. **Predominant agents of mycetoma according to region.**

werneckii in the stratum corneum. Black piedra is associated with the development of focal thickening on the hair shaft and results from colonization of the shaft by *Piedraia hortae*. Cutaneous phaeohyphomycosis involves deeper skin structures and results in dermatomycosis and onychomycosis; this lesion is frequently due to agents such as *Scytalidium* and *Phyllosticta* species.

Subcutaneous phaeohyphomycosis may be confused clinically with chromomycosis. Patients have discrete subcutaneous nodules or cysts that result from direct inoculation or penetrating trauma. The most common organisms are *Exophiala jeanselmei, Exophiala dermatitidis, Alternaria alternans, and Phialophora* species. Mycotic keratitis as a result of infection with *Curvularia, Exophiala*, and *Exserohilum* species may occur after corneal trauma or surgery.

Foreign body–related infections are seen in patients undergoing chronic ambulatory peritoneal dialysis in whom fungal peritonitis develops, in patients with indwelling intravenous catheters, and in other devices such as breast implants.

Fungal sinusitis (Chapter 394) is commonly associated with dematiaceous fungi and can be manifested as allergic fungal sinusitis, a fungus ball in a sinus cavity, and invasive fungal sinusitis associated with extension into bone, soft tissue, and the central nervous system. This destructive process is indistinguishable from that of rhinocerebral zygomycosis (Chapter 312) or invasive *Aspergillus* sinusitis (Chapter 311). *Bipolaris, Curvularia, Exserohilum*, and *Alternaria* species are the most common organisms causing invasive fungal sinusitis.

Systemic phaeohyphomycosis may result from direct extension from a colonized area or dissemination from a distant source. Most patients with systemic disease have significant underlying immunosuppression, and the organisms have a proclivity for involvement of the brain, lungs, endocardium, and other visceral organs. Among patients with primary central nervous system disease, *Cladophialophora bantiana, Rhinocladiella mackenziei,* and *Chaetomium atrobrunneum* are the most common etiologic agents, and the majority of cases are in otherwise healthy patients with little or no underlying immunodeficiency. Among immunocompromised patients, *Verruconis gallopava, Bipolaris* species, and *Exophiala dermatitidis* are seen more commonly.

In severely immunocompromised patients, especially patients who have hematologic malignancies or have received a stem cell transplant with or without prolonged and profound neutropenia, infection with *Lomentospora prolificans* can present as multiorgan dissemination. Infection with this multidrug-resistant pathogen is associated with an exceptionally high mortality rate.

Mycetoma

Mycetoma is a chronic, slowly progressive infection that starts in the subcutaneous tissue and spreads across tissue planes to contiguous structures.[7] The lesion is usually confined to one anatomic site. The clinical manifestations and natural history of mycetoma are variable and, to some degree, related to the pathogenic agent involved. For example, the progression of eumycetoma tends to be slower than that of actinomycetoma. In addition, eumycetoma lesions tend to be more confined and have less inflammation and fewer granulomas and fistulas but more fibrosis compared with actinomycetoma lesions. The foot is the most common site involved in mycetoma (Fig. 314-2), followed by the hands, but any other part of the body may become involved. Painless nodular and/or papular swelling is a common early manifestation of mycetoma, followed by a slow evolution to painless, fixed woody induration. This infection typically runs a chronic, relentless course, sometimes spanning several decades. It is characterized by recurring cycles of suppuration, draining sinuses, bacterial superinfection, and scar formation. Old sinuses close, and new ones occur. Satellite lesions are common. Constitutional symptoms are rare. The presence of fever often indicates bacterial superinfection. Substantial bone involvement mimicking chronic osteomyelitis with cavitary bone lesions, periosteal reaction or sclerosis (seen with radiography, computed tomography, or magnetic resonance imaging [MRI] studies), osteoporosis, and reactive periosteal bone formation may occur. However, pathologic fractures are rare. Because nerves are relatively spared, neuropathic manifestations are uncommon. Inexorable limb deformity and misuse because of destruction of deeper tissues may be seen in chronic, refractory, and advanced cases. Regional lymphadenitis may occur, but mycetoma does not spread hematogenously, so visceral dissemination is not seen.

DIAGNOSIS

The diagnosis of a dematiaceous fungal infection is suggested by direct examination of a clinical specimen with a 10% potassium hydroxide preparation or special stains to demonstrate pigmentation in the cell walls of these organisms. For patients with chromomycosis, the finding of sclerotic cells or copper pennies

FIGURE 314-2. Clinical presentation of mycetoma. A 40-year-old farmer from rural Venezuela with a 10-year history of foot edema and slowly progressive deformity following an injury caused by being struck by a hammer presented with chronic crusted plaques, multiple confluent tender abscesses with fistulization, and release of black grains. The range of motion of the patient's ankle and foot joints was limited, but the joints were not painful. A deep skin biopsy with hematoxylin and eosin staining, periodic acid–Schiff staining, foot radiography, sampling of black grain smears, and a mycology culture were performed. The foot radiograph showed osteofibrosis, destruction of articular surfaces, osteoporosis, and ankylosis, and *Madurella* spp grew in the culture. (Courtesy of Dr. M. Mendoza, Instituto De Biomedicina, Laboratorio de Micología, San Jose Caracas, Venezuela.)

on skin biopsy is characteristic, and special stains are usually unnecessary. For patients with other forms of phaeohyphomycosis, the Fontana-Masson stain is useful in distinguishing organisms with significant melanin content. Culture remains the means by which a specific etiologic diagnosis is established, and the identity of the organism is largely based on colony and microscopic morphology. A reliable polymerase chain reaction–based diagnostic assay was developed for *Exserohilum rostratum* in the context of the fungal meningitis outbreak, but serologic studies and molecular diagnostics are not generally available for other organisms, especially in endemic settings.

The diagnosis of mycetoma is complicated by the fact that nonfungal organisms are frequent etiologic agents. The diagnosis is suspected in the presence of granular drainage from a characteristic skin lesion. However, grains in tissue alone may be difficult to culture because they may be composed of dead organisms. Furthermore, grains may be contaminated by surface bacteria or fungi. Thus, a deep-tissue biopsy specimen is ideal for staining (hematoxylin and eosin, Gram stain, modified Ziehl-Neelsen stain, Gomori methenamine silver, periodic acid–Schiff) and appropriate selective bacterial and fungal cultures. Alternatively, aspiration of grains from unopened sinus tracts can provide suitable material for culture. The culture should be maintained for several weeks because some of the causative agents of mycetoma (e.g., *Nocardia* and *Streptomyces* species) may require 4 to 6 weeks for detection by culture methodology.

Differential Diagnosis

The specific manifestations of chromomycosis, cutaneous and subcutaneous phaeohyphomycosis, and mycetoma are often confused with other entities.[8] It is important to consider benign or malignant skin tumors, other chronic granulomatous lesions (e.g., thorn granuloma), and verrucous leishmaniasis (Chapter 319). Deep skin and subcutaneous infections due to other fungi (e.g., blastomycosis [Chapter 308], sporotrichosis [Chapter 308], cryptococcosis [Chapter 309], and coccidioidomycosis [Chapter 308]), and higher-order bacteria (e.g., nocardiosis [Chapter 306], mycobacteriosis [Chapter 299 and 300]), must be considered. Skin lesions without fistulas can occasionally resemble unusual forms of sporotrichosis (mycetomatous lymphatic sporotrichosis) and granulomatous dermatophyte infections. The latter infection, which is typically seen in Africans and sometimes called pseudomycetoma (Majocchi granuloma), is a painless granulomatous induration of the skin and subcutaneous tissues caused by dermatophytes that may be associated with grains consisting of fungi. Unlike mycetoma, pseudomycetoma is confined to the skin and subcutaneous tissue and does not spread to deeper tissues. Chronic severe botryomycosis (typically caused by *Staphylococcus aureus*; Chapter 267) with purulent exudates, grains, and draining sinus tracts may be confused with mycetoma. Actinomycosis (Chapter 304), which is caused by endogenous microaerophilic actinomycetes, also has a propensity for grains and formation of draining sinus tracts, but its location is characteristic in

the neck, chest, abdomen, and pelvis. Differentiation between mycetomas with bone involvement and chronic osteomyelitis or osseous tumors may be challenging. Ultrasonography has been used to reliably differentiate mycetoma from either tumor or osteomyelitis.[9] The dot-in-circles sign seen on MRI (tiny hypodense foci, representing grains, within high-hyperintensity spherical lesions, representing granulomas, scattered by areas of fibrosis) may provide an early and specific diagnostic clue for mycetoma.

TREATMENT

Chromomycosis

For chromomycosis, surgical excision of a cutaneous or subcutaneous lesion is often curative,[10] although antifungal therapy (Chapter 307) is usually given in conjunction with surgery. The triazoles, including itraconazole (200 mg orally twice daily), voriconazole (200 mg twice daily), and posaconazole (300 mg daily), demonstrate the best in vitro activity, although clinical studies with these agents are very limited. Terbinafine (500 mg orally twice daily) is an effective alternative for chromomycosis. Duration of therapy, with or without surgical excision, is generally 3 to 12 months, depending on clinical response.

Phaeohyphomycosis

For phaeohyphomycosis, the orally available expanded-spectrum triazoles, including itraconazole (200 mg twice daily), voriconazole (200 mg twice daily), posaconazole (300 mg daily), and isavuconazole (372 mg once daily), demonstrate excellent in vitro activity against the most common pathogenic dematiaceous fungi.[11] Regardless of which of these agents is selected, the recommended duration of treatment is at least 6 months. Amphotericin B has modest in vitro activity against most of these fungi and is usually reserved for patients with life-threatening or disseminated disease. Amphotericin B is administered as 0.6 to 1.0 mg/kg daily for up to 6 weeks to gain control of the infection before transitioning to oral therapy with an azole, usually to complete a dependent 6-month course of therapy but sometimes as longer term chronic suppressive therapy.

Most patients with epidemic *Exserohilum rostratum* infections have been treated successfully with voriconazole 4 mg/kg twice daily (intravenous, then oral) for up to 6 months, with or without a lipid formulation of amphotericin B (3 to 5 mg/kg daily), for severe central nervous system involvement. Posaconazole (300 mg orally daily for up to 6 months) has been used as salvage therapy for patients who are intolerant to voriconazole or in whom voriconazole has failed, and isavuconazole is also an option.[12]

The length of antifungal therapy for any of the systemic phaeohyphomycoses is unclear. However, therapy should probably be continued for at least 4 to 6 months or until 1 month after resolution of all signs and symptoms of disease.

Mycetoma

For mycetoma, therapy is individualized because no therapy had been proven to be preferred. Treatment is dependent upon distinguishing actinomycetoma from eumycetoma, identification of the causative pathogen, and the extent of tissue invasion.[13]

For actinomycetoma, optimal treatment consists of antimicrobial therapy (at least 5 to 6 weeks) in conjunction with limited debulking surgery in selected cases. Trimethoprim-sulfamethoxazole (2 double-strength tablets twice daily for 5 weeks) plus amikacin (7.5 mg/kg twice daily for 3 weeks) is usually successful. Alternative options include a combination of tetracycline (100 mg twice daily), dapsone (100 mg daily), and/or rifampin (600 mg daily), each administered orally, together with intramuscular streptomycin (0.5 to 1 g daily) for 4 to 6 weeks. These agents are used in different sequences and combinations depending on the organism (e.g., trimethoprim-sulfamethoxazole with or without dapsone for *Nocardia* species (Chapter 306), streptomycin or amikacin with dapsone for *A. madurae*). Parenteral streptomycin is usually reserved for refractory cases that do not respond to oral therapy. Response to therapy is slow (usually within 4 weeks), and relapse is common. Several cycles of therapy may be necessary for chronic recurrent disease.

The best treatment results for eumycetoma have been achieved with at least 9 to 12 months of agent such as ketoconazole (200 to 400 mg daily) or itraconazole (200 to 400 mg daily), combined with appropriate surgery. In vitro activity and clinical experience with the newer azoles (voriconazole, débridement, and isavuconazole) and terbinafine are promising, but data are very limited. Clinical results with amphotericin B for refractory cases have been generally disappointing, and many of the causative agents demonstrate in vitro resistance to this compound.

Surgery often plays a pivotal role in eumycetoma because most disease is refractory to antifungal therapy alone. The need and extent of surgery depend on the specific agent and the degree of tissue invasion. Wide-margin surgery for localized lesions is usually curative. Extensive débridement and disfiguring surgery are reserved for severe and refractory cases.

PREVENTION

Mycetoma is a frequently ignored infection despite the significant socioeconomic burden it causes in many impoverished regions of the world. No preventive measures are of proven efficacy, but consistent use of footwear seems advisable, because minor trauma is an important predisposition to development of foot mycetoma.

PROGNOSIS

The prognosis for mycetoma depends on the anatomic site and degree of tissue involvement.[14] Extension into bony structures is associated with the worst long-term consequences, so early diagnosis and intervention are critical in optimizing outcomes.

315 ANTIPARASITIC THERAPY

PHILIP J. BUDGE AND RICHARD D. PEARSON

Although substantial progress has been made in reducing the impact of protozoal and helminthic infections, parasitic diseases remain a major cause of morbidity and mortality worldwide, particularly in impoverished tropical regions. In the United States, parasitic diseases are most often encountered among immigrants and international travelers to endemic areas and among a growing number of persons with compromised immunity due to human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS), organ transplants, immunosuppressive medications, neoplasms, or other causes. A number of drugs (Table 315-1) are available to treat protozoal and helminthic diseases, but physicians practicing in industrialized countries may not be familiar with their use. This chapter focuses on their therapeutic indications, pharmacology, and major side effects. Generalizations emerge that help in organizing an otherwise vast array of information.

Detailed information about the diagnosis and treatment of specific parasitic diseases can be found in the chapters to follow and from the U.S. Centers for Disease Control and Prevention (CDC) (see A-Z Index; https://www.cdc.gov/parasites/az/index.html).[1] Many antiparasitic drugs are commercially available in the United States, whereas others can only be obtained directly from the manufacturer, special pharmacies, or the CDC Drug Service through investigational new drug protocols. Major challenges in recent years have arisen from a shortage of some antiparasitic drugs and, in the United States, massive increases in the cost of others. Some drugs used to treat bacterial or fungal pathogens are also effective in the treatment of parasitic diseases (see Chapters 266 and 307).

PROTOZOAL DISEASES

MALARIA (*PLASMODIUM* SPECIES): TREATMENT AND PREVENTION

Most drugs that are available for the treatment and prophylaxis of malaria act on *Plasmodium* species within erythrocytes. The antimalarial drug of choice depends on the infecting species and the likelihood of resistance (Chapter 316). Resistance to chloroquine is widespread among *Plasmodium falciparum* in most regions of the world and well documented in *Plasmodium vivax* in some areas. Artemisinin-based combination therapy (ACT), including the fixed drug combination artemether-lumefantrine, is the treatment of choice for acute malaria acquired in areas with chloroquine resistance. The fixed drug combination atovaquone-proguanil or the antibiotic doxycycline is commonly used for prophylaxis in travelers to areas with chloroquine-resistant *Plasmodium* species. Chloroquine is used for treatment and prophylaxis only in areas where *Plasmodium* species are sensitive. Only primaquine and tafenoquine kill hypnozoites of *P. vivax* and *Plasmodium ovale* in the liver. Country-specific recommendations for prophylaxis and treatment are provided by the CDC (www.cdc.gov/travel/) and in "CDC Health Information for International Travel 2020."[2]

ABSTRACT

Parasitic infections remain a major cause of morbidity and mortality worldwide, particularly in impoverished tropical regions. It is helpful to group parasitic diseases and treatment into those caused by protozoa, single-celled organisms that multiply by cell division, and helminths, multicellular worms and flukes with complex internal structures. The most important protozoal diseases are attributable to members of the Apicomplexa that cause malaria, babesiosis, toxoplasmosis, and cryptosporidiosis and to the Kinetoplastida that are responsible for Chagas disease, human African trypanosomiasis (sleeping sickness), and leishmaniasis. Ameba and other types of protozoa also are important human pathogens. Helminths are subdivided into nematodes, or roundworms, which can be grouped into those that live in the gastrointestinal tract or elsewhere in the body, and platyhelminths, or flat worms, which are subdivided into cestodes, or tapeworms, and trematodes, or flukes. Depending on the helminth, albendazole, diethylcarbamazine, ivermectin, praziquantel, or another drug is used. Shortages of some antiparasitic drugs and substantial increases in the cost of others complicate therapy. Many antiparasitic drugs are commercially available in the United States; others can only be obtained from the Centers for Disease Control and Prevention Drug Service.

KEYWORDS

artemisinin-based combination therapy
granulomatous amebic encephalitis
leishmaniasis
malaria
miltefosine

TABLE 315-1 TREATMENT OF PARASITIC DISEASES

DRUG	INDICATIONS AND COMMENTS	USUAL ADULT DOSAGES
1. MALARIA (*PLASMODIUM* SPECIES): TREATMENT AND PREVENTION		
Artemether-lumefantrine	Uncomplicated malaria treatment (in combination with primaquine if *P. vivax* or *P. ovale*)	4 tablets (20 mg artemether/120 mg lumefantrine) PO per dose × 6 doses
Artesunate	Severe malaria: duration depends on response and ability to tolerate PO therapy	2.4 mg/kg/dose IV q12h
Atovaquone-proguanil	Malaria prophylaxis; begin 2 days prior to travel and continue through 1 week post-travel Malaria treatment (use in combination with primaquine if *P. vivax* or *P. ovale*)	1 tablet (250 mg atovaquone/100 mg proguanil) PO daily 4 tablets (250 mg atovaquone/100 mg proguanil) PO daily × 3 days
Chloroquine	Malaria prophylaxis (ONLY in areas of known susceptibility); begin 2 weeks prior to travel and continue through 4 weeks post-travel	500 mg (300 mg base) weekly
Clindamycin	Malaria treatment (in combination with quinine sulfate or primaquine)	20 mg/kg/day PO divided q8h × 7 days
Doxycycline	Malaria prophylaxis; begin 2 days prior to travel and continue through 4 weeks post-travel Malaria treatment (in combination with quinine sulfate or primaquine)	100 mg PO daily 100 mg IV or PO bid × 7 days
Hydroxychloroquine	Malaria prophylaxis (ONLY in areas of known susceptibility); begin 2 weeks prior to travel and continue through 4 weeks post-travel	400 mg PO once weekly
Mefloquine	Malaria prophylaxis; begin 2 weeks prior to travel and continue through 4 weeks post-travel Malaria treatment (use in combination with primaquine if *P. vivax* or *P. ovale*)	250 mg PO weekly 750 mg PO once followed by 500 mg PO 6-12 hours later
Primaquine	Malaria prophylaxis; begin 2 days prior to travel and continue through 1 week post-travel Malaria treatment (*P. vivax* or *P. ovale*) or presumptive anti-relapse therapy	30 mg once daily 30 mg once daily × 14 days (in combination with another appropriate agent)
Tafenoquine	Malaria prophylaxis; begin 3 days prior to travel and continue through 1 week post-travel Malaria presumptive anti-relapse treatment (*P. vivax* or *P. ovale*)	200 mg PO daily × 3 doses, then 200 mg PO weekly 300 mg PO once, taken after leaving malarious area
Quinidine gluconate	Malaria treatment (switch to oral therapy one parasitemia <1% and patient tolerating PO)	324 mg IV q8-12h
Quinine sulfate	Malaria treatment (in combination with doxycycline, tetracycline, or clindamycin)	648 mg PO q8h × 3-7 days
2. TOXOPLASMOSIS, BABESIOSIS, AND AMOEBIC ENCEPHALITIS		
Atovaquone	Babesiosis (in combination with azithromycin); longer duration may be necessary in patients at high risk of relapse Toxoplasmosis prophylaxis (either as monotherapy or in combination with pyrimethamine and leucovorin) Toxoplasmosis treatment (alternative agent, used in combination with pyrimethamine plus leucovorin, or with sulfadiazine)	750 mg PO bid × 7-10 days 1.5 g PO daily 1.5 g PO bid
Azithromycin	Babesiosis (in combination with atovaquone); longer duration may be necessary in patients at high risk of relapse	500 mg IV or PO × 1, then 250-500 mg IV or PO daily × 7-10 days
Clindamycin	Babesiosis (in combination with quinine); longer duration if high risk of relapse Toxoplasmosis encephalitis or pneumonitis (in combination with pyrimethamine and leucovorin)	600 mg IV q6h-q8h × 7-10 days 600 mg IV q6h × 6 weeks or longer
Dapsone	Toxoplasmosis prophylaxis (in combination with pyrimethamine and leucovorin)	50 mg PO daily or 200 mg PO weekly
Miltefosine	Free-living amoeba infections (*Naegleria, Balamuthia, Acanthamoeba*) including amoebic encephalitis, in combination with other medications	50 mg PO bid (<45 kg) or tid (>45 kg)
Pyrimethamine	Toxoplasmosis prophylaxis (in combination with dapsone and leucovorin) Toxoplasmosis encephalitis treatment (in combination with sulfonamide or clindamycin, and leucovorin)	50-75 mg PO weekly 25-75 mg PO daily
Spiramycin	Acute toxoplasmosis of pregnancy	1 g q8h
Sulfadiazine	Toxoplasmosis encephalitis (in combination with pyrimethamine and leucovorin, or in combination with atovaquone)	1-1.5 g PO q6h (acute) or 2-4 g daily in 2-4 divided doses
Trimethoprim/sulfamethoxazole	Toxoplasmosis prophylaxis Toxoplasmosis encephalitis treatment (alternative agent)	1 DS tablet daily or 1 DS tablet 3 times weekly or 1 SS tablet daily 10 mg/kg/day (TMP component) IV or PO in 2 divided doses × ≥6 weeks
Quinine sulfate	Babesiosis (in combination with clindamycin); longer duration if high risk of relapse	650 mg PO q6-8h × 7-10 days
3. INTESTINAL AND VAGINAL PROTOZOA		
Chloroquine	Extraintestinal amebiasis	1 g (600 mg base) daily × 2 days, then 500 mg daily × 2-3 weeks
Ciprofloxacin	Cystoisosporiasis in patients with HIV (if sulfa-intolerant)	500 mg PO bid × 7-10 days
Diloxanide furoate	Intestinal amebiasis	500 mg PO tid × 10 days
Metronidazole	Amebiasis, intestinal or liver abscess (followed by an intraluminal agent such as paromomycin) Intestinal protozoa (balantidiasis, *Dientamoeba fragilis*, giardiasis)	500-750 mg PO q8h × 7-10 days 500-750 mg PO tid × 5-10 days

TABLE 315-1 TREATMENT OF PARASITIC DISEASES—cont'd

DRUG	INDICATIONS AND COMMENTS	USUAL ADULT DOSAGES
Nitazoxanide	Giardiasis Cryptosporidiosis (immunocompetent) Cryptosporidiosis (immunosuppressed)	500 mg PO q12h × 3 days 500 mg PO q12h × 3 days 500 mg-1 g q12h × 14 days
Paromomycin	Intestinal amebiasis (luminal agent) Cryptosporidiosis-associated diarrhea in patients with HIV	25-35 mg/kg PO daily in 3 divided doses × 5-10 days 500 mg PO qid × 14-21 days
Pyrimethamine	Cystoisosporiasis in patients with HIV (in combination with leucovorin)	50-75 mg (treatment) or 25 mg (secondary prophylaxis) PO daily
Tinidazole	Giardiasis, trichomoniasis (initial infection) Intestinal amebiasis, amebic liver abscess Trichomoniasis (persistent or recurrent)	2 g PO single dose 2 g PO daily × 3-5 days 2 g PO daily × 7 days
4. TRYPANOSOMIASIS AND LEISHMANIASIS		
Benznidazole	American trypanosomiasis (Chagas disease)	5-7 mg/kg/day PO in 2 divided doses × 60 days
Eflornithine	Human African trypanosomiasis (with CNS involvement) monotherapy Human African trypanosomiasis (with CNS involvement) in combination with nifurtimox	100 mg/kg/dose q6h × 14 days 200 mg/kg/dose q12h × 7 days
Fexinidazole	Human African trypanosomiasis (reduce dose to 1.2 g followed by 600 mg if <35 kg)	1.8 g PO daily × 4 days, then 1.2 g daily × 6 days
Liposomal Amphotericin B	Leishmaniasis; schedule and duration vary by disease type (visceral, mucocutaneous, or cutaneous) and immune status	2-4 mg/kg/day IV
Melarsoprol	Human African trypanosomiasis (with CNS involvement)	2-3.6 mg/kg IV daily
Miltefosine	Leishmaniasis	50 mg PO bid (<45 kg) or tid (≥45 kg) duration varies with disease type and immune status
Nifurtimox	Human African trypanosomiasis (with CNS involvement) in combination with eflornithine American trypanosomiasis (Chagas disease)	15 mg/kg/day PO in 3 divided doses × 10 days 8-10 mg/kg/day PO in 3-4 divided doses × 90 days
Pentamidine	Human African trypanosomiasis (without CNS involvement)	4 mg/kg IV daily × 7 days
Stibogluconate sodium	Leishmaniasis; duration varies by disease type (visceral, mucocutaneous, or cutaneous) and immune status	20 mg/kg/day IV/IM
Suramin	Human African trypanosomiasis (without CNS involvement)	4-5 mg/kg IV once (test dose), then 20 mg/kg (max. 1 g/dose) IV on days 1, 3, 7, 14, and 21
5. HELMINTHIC DISEASES (ROUNDWORMS, TAPEWORMS, AND FLUKES)		
Albendazole	Many nematode infections, including ascariasis and pinworm (for pinworm, repeat in 2 weeks) Cutaneous larva migrans Trichuriasis (whipworm), often in combination with ivermectin Toxocariasis (visceral larva migrans, occular larva migrans) Some cestode infections, including gnathostomiasis, echinococcosis, and neurocysticercosis (in combination with praziquantel and corticosteroids); microsporidiosis Trichinellosis	400 mg PO single dose 400 mg PO daily × 3 days 400 mg PO daily × 3 days 400 mg PO bid × 5 days to 2 weeks 400 mg PO bid × 10 days (or longer) 200-400 mg PO tid × 3 days, then 400-500 mg tid × 10 days
Diethylcarbamazine (DEC)	Lymphatic filariasis elimination programs, in combination with albendazole and/or ivermectin; may NOT be used where onchocerciaisis or loiasis are co-endemic Lymphatic filariasis, including tropical pulmonary eosinophilia; contraindicated if concurrent onchocerciasis or loiasis Loiasis in patients with microfilarial blood counts <2500; available only through consultation with CDC	6 mg/kg PO single dose, annually 6 mg/kg PO daily in 3 divided doses × 12-21 days 9 mg/kg PO daily in 3 divided doses × 21 days; begin with 1 mg/kg daily and increase to full dose by day 4
Ivermectin	Onchocerciasis and/or lymphatic filariasis elimination, usually in combination with albendazole Ascariasis Stronglyloidiasis, gnathostomiasis (without CNS involvement) Lice, scabies, skin mites	150-200 mcg/kg PO single dose, annually 200 mcg/kg PO single dose 200 mcg/kg PO daily × 2 doses (uncomplicated infection) or until symptoms resolve and stool/sputum are negative for at least 2 weeks (hyperinfection syndrome) 200-400 mcg/kg PO weekly × 2-3 doses
Mebendazole	Pinworm (repeat in 2 weeks) Ascariasis, hookworm, trichuriasis (whipworm) Toxocariasis (visceral larval migrans) Capillariasis	100 mg PO single dose 500 mg PO single dose OR 100 mg PO bid × 3 days 100-200 mg PO bid × 5 days 200 mg PO bid × 20 days
Moxidectin	Onchocerciasis elimination	8 mg PO single dose, annually
Praziquantel	Intestinal tapeworms (hymenolepsiasis, taeniasis, diphyllobothriasis) Chlonorchis/opisthorchis Schistosomiasis Neurocysticercosis (usually in combination with albendazole and corticosteroids); expert consultation advised.	5-25 mg/kg PO single dose 25 mg/kg/dose PO tid × 1-2 days 40-60 mg/kg/day PO in 2-3 divided doses × 1 day 50 mg/kg/day PO in 3 divided doses × 10-14 days
Pyrantel pamoate	Ascariasis, trichostrongylus, pinworm (repeat in 2 weeks) Hookworm	11 mg/kg PO single dose 11 mg/kg PO daily × 3 days
Triclabendazole	Fascioliasis (liver fluke)	10 mg/kg PO q12h × 2 doses

bid = twice daily; CDC = Centers for Disease Control and Prevention; CNS = central nervous system; DS = double strength; HIV = human immunodeficiency virus; IM = intramuscularly; IV = intravenously; PO = orally; tid = 3 times daily; TMP = trimethoprim.

Dosing reference: Lexicomp. *Adult Drug Information: A Clinically Relevant Resource for All Healthcare Professionals*, 30th ed. Wolters Kluwer.

Artemisinins and Artemisinin Combination Therapy

Artemisinins are the most rapidly acting drugs available for the treatment of malaria.[A1] They are sesquiterpene lactone derivatives of the wormwood plant *Artemisia annua*, from which qinghaosu, the Chinese herbal medication for fever, is derived. Artemisinins are endoperoxide-containing compounds. In the presence of intraparasitic iron, they are converted into free radicals and other intermediates that alkylate specific malarial proteins and act rapidly to kill intraerythrocytic parasites. The artemisinins are administered with a second antimalarial drug that has a different mechanism of action and longer half-life to prevent the development of resistance. The route of administration of artemisinins varies; some are well absorbed orally, whereas others must be administered intravenously, intramuscularly, or by suppository. Their short half-lives preclude their use for prophylaxis. Side effects in humans are common but seldom result in discontinuation of treatment.

Artemether-Lumefantrine

Artemether-lumefantrine, a fixed drug combination, is used throughout the world (including the United States) to treat chloroquine-resistant malaria. It is taken with food, but grapefruit juice should be avoided. Common adverse reactions in adults are headache, anorexia, dizziness, asthenia, arthralgia, and myalgia. The most common adverse reactions in children are fever, cough, vomiting, anorexia, and headache. These side effects do not usually result in discontinuation of therapy. Of greater concern, lumefantrine can prolong the QT interval and is contraindicated in persons with an abnormal QTc. Lumefantrine also inhibits CYP206 and can thereby reduce the metabolism of other medications, including those that prolong the QTc. It can also decrease the effectiveness of birth control pills. Care must be taken to review the recipient's medication list for potential interactions.

Artesunate

Artesunate, which is the only available recommended therapy for severe malaria in the United States,[3] is commercially available and also available from the CDC under emergency conditions (contact the CDC Malaria Hotline for information at 770-488-7788 weekdays and 770-488-7100 nights/weekends and ask for the on-call malaria expert). Studies in malaria-endemic regions suggest that parenteral artesunate has a higher success rate and lower adverse event rate than quinidine. In addition to the side effects of artemether, artesunate has been associated with delayed hemolysis (unrelated to glucose-6-phosphate dehydrogenase [G6PD] deficiency) up to 4 weeks after therapy.

Quinine and Its Derivatives

Chloroquine

Widespread resistance among *P. falciparum* and, in some locations (especially Papua New Guinea and Indonesia), among *P. vivax* limits the utility of chloroquine. Its half-life, which varies among persons, averages 4 days, thereby permitting once-weekly administration for prophylaxis. Chloroquine is concentrated in the hemoglobin-containing digestive vesicles of asexual intraerythrocytic parasites. It inhibits the parasite's heme polymerase that incorporates ferriprotoporphyrin type IX complexes, which are potentially toxic to the parasite, into insoluble, nontoxic, crystalline hemozoin. Chloroquine-resistant strains of *P. falciparum* actively transport chloroquine out of the intraparasitic compartment.

Chloroquine is generally well tolerated when used at the doses recommended for the prophylaxis and treatment of malaria. Side effects include headache, nausea, vomiting, blurred vision, dizziness, and fatigue. Some patients with African ancestry experience pruritus, which responds to antihistamines. Rare side effects include depigmentation of hair, exacerbation of psoriasis, blood dyscrasias, seizures, neuropsychiatric effects, and reactions in persons with porphyria. Retinal damage has occurred in persons receiving chloroquine at high doses for the treatment of rheumatologic disorders, but it has not been documented as a problem in those taking it weekly over a period of many years for malaria prophylaxis. Cardiopulmonary collapse and death can occur after accidental overdose and in adults attempting suicide. As little as 5 g of chloroquine can be fatal unless treatment is promptly initiated with mechanical respiration, anticonvulsants, and blood pressure support.

Hydroxychloroquine

Hydroxychloroquine, which is used for rheumatologic diseases, is also effective against chloroquine-sensitive *Plasmodium* species. The side effects are similar to those of chloroquine.

Mefloquine

Mefloquine, a quinoline methanol compound derived from quinine, is occasionally used for the treatment of chloroquine-resistant *P. falciparum* malaria, but concern about neuropsychiatric and other toxicities and the availability of better alternatives now limit its use. Mefloquine is available for oral administration only. Slowly and incompletely absorbed, it is 99% protein bound. It has a variable half-life ranging from 6 to 23 days with a mean of approximately 14 days. It is metabolized and excreted slowly through bile and feces. It is associated with nausea, dizziness, vivid dreams, fatigue, and lassitude. Less common side effects, but of greater concern, are anxiety, depression, acute psychosis, and seizures. Mefloquine is contraindicated in persons with a history of epilepsy or psychiatric disorders. It also depresses atrioventricular conduction and should not be used in persons taking β-blockers for cardiac indications. Mefloquine now carries a U.S. Food and Drug Administration (FDA) black-box warning. Although not approved for use during pregnancy or in children weighing less than 15 kg, mefloquine has been used in these situations when its potential benefits are judged to outweigh its risks. It has been reported to have no adverse effects on pregnancy outcomes (such as stillbirths and abortions) and no effects on low birth rate and prematurity.[4]

Primaquine

Primaquine, an 8-aminoquinoline, kills the hypnozoite stage of *P. vivax* and *P. ovale* in the liver. Primaquine is used as a 14-day course at the end of treatment or prophylaxis to prevent late relapses in persons who are or may have been infected with these *Plasmodium* species. It is also an alternative for daily primary prophylaxis for *P. vivax*[A2] and other species. In that case, it is begun 1 or 2 days before exposure and continued during and for 7 days after a traveler leaves a malaria-endemic area.

Primaquine is absorbed orally and rapidly converted to carboxyprimaquine, which has a half-life of approximately 7 days. It is generally well tolerated, although some recipients experience abdominal cramps, epigastric distress, and nausea. The major concern with primaquine is hemolysis in persons with G6PD deficiency (Chapter 147). The G6PD status of the recipient must be determined before it is administered. Rarely, primaquine causes neutropenia, methemoglobinemia, hypertension, or arrhythmias. Primaquine is contraindicated during pregnancy and in breast-feeding mothers because life-threatening hemolysis may occur if the fetus or baby is deficient in G6PD.

Tafenoquine

Tafenoquine, which is an analogue of primaquine, is administered as a single 300-mg dose following treatment of acute malaria due to *P. vivax* and *P. ovale* to prevent relapse. It can also be used for primary prophylaxis in travelers; 200 mg daily for 3 days before travel, then once weekly while in the malarious region, then in the week following exit, a final dose 7 days after the previous dose in the malarious region.[5]

Tafenoquine is better absorbed than primaquine, has a half-life of approximately 15 days, and is less likely to cause gastrointestinal problems. Tafenoquine can cause severe psychiatric reactions and is contraindicated in persons with a history of psychiatric disorder. Tafenoquine also can cause hemolysis in patients with G6PD deficiency and is contraindicated during pregnancy and breast-feeding.

Quinine Sulfate and Quinidine Gluconate

Quinine sulfate, a cinchona alkaloid, is the oldest of the antimalarials. It is rapidly absorbed after oral administration and has a half-life of 16 to 18 hours in persons with malaria. Quinine has the poorest therapeutic to toxicity ratio of any antimalarial drug. The side effects, known collectively as cinchonism, include tinnitus, decreased hearing, headache, nausea, vomiting, dysphoria, and visual disturbances. They are dose related and reversible. Quinine has also been associated with severe hypoglycemia in persons with heavy *P. falciparum* infections as a result of the utilization of glucose by intraerythrocytic *Plasmodium* and release of insulin from the pancreas. Hypoglycemia can be treated and prevented by the intravenous administration of glucose. Rare complications with quinine include massive hemolysis in patients with heavy *P. falciparum* infection resulting in hemoglobinuria and renal failure (blackwater fever), cutaneous hypersensitivity reactions, agranulocytosis, and hepatitis. Quinine can cause respiratory paralysis in persons with myasthenia gravis. It stimulates uterine contractions during pregnancy and can result in abortion, but it has saved the lives of many pregnant women with *P. falciparum* malaria. Quinine dihydrochloride given intravenously can cause myocardial depression, peripheral vascular collapse, respiratory depression, and potentially death. Quinidine

gluconate, the stereoisomer of quinine, administered intravenously for the treatment of malaria is no longer available in the United States.

Atovaquone-Proguanil

Atovaquone-proguanil, a fixed drug preparation, is used for the treatment of uncomplicated, chloroquine-resistant and -sensitive malaria, as well as prophylaxis. Atovaquone is a highly lipophilic compound with low aqueous solubility. Administration with food enhances its absorption two-fold. Plasma concentrations do not increase proportionately with dose. Atovaquone is highly protein bound with a half-life exceeding 60 hours. It undergoes extensive enterohepatic cycling and is eventually excreted unchanged in feces. Atovaquone selectively inhibits electron transport in the mitochondria of susceptible *Plasmodium* at the level of the cytochrome bc_1 complex, thereby resulting in collapse of the mitochondrial membrane potential. It also affects pyrimidine biosynthesis, which is obligatorily coupled to electron transport in *Plasmodium*.

Atovaquone is generally well tolerated but can cause nausea, vomiting, diarrhea, rash, and pruritus. Unfortunately, resistance develops rapidly when atovaquone is used alone to treat malaria.

Proguanil is absorbed slowly after oral administration. The serum level falls to zero within 24 hours, so it must be administered daily. Its triazine metabolite, cycloguanil, inhibits dihydrofolate reductase in susceptible *Plasmodium* species. Resistance is well documented when proguanil is used alone. In addition, proguanil acts synergistically with atovaquone to collapse the mitochondrial membrane potential in susceptible *Plasmodium* species.

The combination of atovaquone-proguanil is the best tolerated of the options for prevention of chloroquine-resistant malaria. It is begun 1 to 2 days before departure and continued during the time of exposure and for 7 days thereafter. Higher doses of atovaquone-proguanil, administered over a 3-day period, are used to treat acute, uncomplicated malaria. Potential side effects include abdominal pain, nausea, vomiting, diarrhea, headache, pruritus, and rash. Asymptomatic, transient elevations in liver enzymes have been observed with treatment doses.

Doxycycline and Tetracycline

Doxycycline (100 mg daily) provides effective prophylaxis against all *Plasmodium* species. It is begun 1 to 2 days before exposure and continued during the time of exposure and for 4 weeks after departure from a malaria-endemic area. Doxycycline or tetracycline can also be administered with quinine to treat acute chloroquine-resistant malaria, but neither doxycycline nor tetracycline acts rapidly enough to be used alone for treatment. Doxycycline is generally well tolerated, although it can cause gastrointestinal symptoms and "pill" esophagitis. To avoid the latter, it should be taken with a full glass of water, and the recipient should remain upright for an hour or more after ingestion. Other important potential side effects include photosensitivity dermatitis, *Candida albicans* vaginitis, and *Clostridioides difficile* colitis. Finally, doxycycline and tetracycline should not be used in children younger than 8 years or in women who are pregnant or breast-feeding unless the potential benefits outweigh the risks.

TOXOPLASMOSIS, BABESIOSIS, AND AMOEBIC ENCEPHALITIS

Toxoplasma gondii (Chapter 320) and *Babesia* species (Chapter 324) are other important pathogens of the phylum Apicomplexa. Pyrimethamine and sulfadiazine, which are useful to treat toxoplasmosis, inhibit sequential steps in the folic acid metabolic pathway. Pyrimethamine preferentially inhibits dihydrofolate reductase. It is well absorbed orally. The major side effect is macrocytic anemia, which can be prevented by the concurrent administration of leucovorin. Sulfonamides reduce the activity of dihydropteroate synthetase and the binding of *p*-aminobenzoic acid to it. In ocular toxoplasmosis with macular involvement, corticosteroids are used along with anti-*Toxoplasma* (Chapter 320) therapy to minimize the local inflammatory response. Clindamycin plus pyrimethamine or atovaquone plus pyrimethamine are therapeutic options in sulfonamide-intolerant patients. Patients with AIDS, $CD4^+$ counts less than 100/μL, and serologic evidence of *T. gondii* infection should receive prophylaxis with one of the following regimens: daily trimethoprim-sulfamethoxazole, pyrimethamine (with leucovorin) plus dapsone, pyrimethamine (with leucovorin) plus atovaquone, or atovaquone alone. Spiramycin, a macrolide, is used for the treatment of toxoplasmosis during pregnancy. Pyrimethamine is currently in short supply. Trimethoprim-sulfamethoxazole is a potential alternative when it is not available.

Two therapeutic regimens are available for babesiosis (Chapter 324). The combination of clindamycin plus quinine is usually used in persons with severe babesiosis, but side effects are common. Long-term treatment (≥6 weeks) is often necessary for immunocompromised patients. Atovaquone plus azithromycin is better tolerated and used for less severe babesiosis (Chapter 324). Clofazimine has been used successfully to treat babesiosis in severely immunocompromised patients.[6]

The addition of miltefosine, an FDA-approved antileishmanial drug,[7] to multidrug regimens has improved the likelihood of survival in persons with granulomatous amebic encephalitis due to *Acanthamoeba* or *Balamuthia*. It is now recommended as part of multidrug regimens to treat granulomatous amebic encephalitis as well as primary amebic meningoencephalitis due to *Naegleria*.[8]

INTESTINAL AND VAGINAL PROTOZOA

Several major luminal pathogens, including *Entamoeba histolytica* (Chapter 323), *Giardia lamblia* (Chapter 322), and *Trichomonas vaginalis* (Chapter 324), live in anaerobic conditions in the intestine or vagina. The 5-nitroimidazoles, metronidazole and tinidazole, are first-line therapy for them, but refractory giardiasis and trichomoniasis are documented. Tinidazole has more favorable pharmacodynamics and is generally better tolerated. Because neither metronidazole nor tinidazole reliably eradicates cysts of *E. histolytica* in the colon, either paromomycin, a poorly absorbed aminoglycoside, or iodoquinol, both of which are active in the lumen of the bowel, should be administered as well. Either one of these drugs or diloxanide furoate is used alone to treat persons with asymptomatic cyst excretion.

Giardiasis can also be treated with nitazoxanide. Nitazoxanide, which is the only drug effective in the treatment of cryptosporidiosis (Chapter 321), can cure immunocompetent persons but not patients who are immunodeficient. The combination of antiretroviral therapy (Chapter 357) plus nitazoxanide may improve symptoms in persons who have HIV and cryptosporidium-related diarrhea, but relapses can occur if the immune status deteriorates. Trimethoprim-sulfamethoxazole, which inhibits successive steps in the folic acid pathway, is the drug of choice for *Cystoisospora* (*Isospora*) *belli* and *Cyclospora cayetanensis* (Chapter 324). Ciprofloxacin is a second-line alternative for the former. Either tetracycline, metronidazole, or nitazoxanide can be used to treat symptomatic *Balantidium coli* infection.

Metronidazole is rapidly absorbed after oral administration and has a half-life of 8 hours. More than half of each dose is metabolized in the liver. The metabolites and remaining parent drug are excreted in urine. Metronidazole is activated by reduction of its 5-nitro group through a sequence of intermediate steps involving microbial electron transport proteins of low redox potential. It is concentrated in susceptible anaerobic organisms and serves as an electron sink. Nausea, vomiting, diarrhea, and a metallic taste are often associated with the use of metronidazole. They are less common, with the lower doses recommended for the treatment of giardiasis than with the higher doses used for amebiasis. Other untoward effects include headache, dizziness, vertigo, and numbness. Potentially severe disulfiram-like reactions occur in patients who ingest alcohol while taking metronidazole.

Tinidazole has a similar mechanism of action and spectrum of activity as metronidazole, but it has more favorable pharmacodynamics and is generally better tolerated. It has been used widely around the world for the treatment of giardiasis, intestinal amebiasis, and trichomoniasis and is preferred over metronidazole for treating giardiasis. In comparison with metronidazole, it has a longer half-life, a shorter and less complicated dosing regimen, and fewer gastrointestinal side effects. It, too, can cause severe disulfiram-like reactions after alcohol ingestion.

TRYPANOSOMIASIS AND LEISHMANIASIS

The Kinetoplastida (*Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense*, which cause human African trypanosomiasis [sleeping sickness; Chapter 317]; *Trypanosoma cruzi*, the etiology of Chagas disease [Chapter 318]; and *Leishmania* species, which cause cutaneous, mucosal, and visceral leishmaniasis [Chapter 319]) often pose substantial therapeutic challenges.

African Trypanosomiasis (Sleeping Sickness)

Fexinidazole, suramin, pentamidine, eflornithine, and melarsoprol are used for the treatment of human African trypanosomiasis (Chapter 317). Fexinidazole is the first all-oral treatment for human African trypanosomiasis and is the WHO-recommended therapy for *T. brucei gambiense* in patients >6 years of age and in first stage (hemolymphatic) or nonsevere second stage (central nervous system [CNS] involvement but <100 leukocytes in cerebrospinal fluid [CSF]) disease. Fexinidazole must always be taken with food because its absorption is insufficient on an empty stomach and will not result in therapeutic levels,

especially in the CNS. For *T. brucei gambesiense* patients with severe stage II disease (>100 WBC in CSF), combination therapy with nifurtimox-eflornithine is preferred.[9] Where fexinidazole is not available, suramin or pentamidine is recommended for the hemolymphatic stage of *T. brucei rhodesiense* and *T. brucei gambiense*, respectively. Both drugs are associated with potentially serious side effects, and suramin can cause severe reactions in persons co-infected with *Onchocerca volvulus*.

Eflornithine, which is much better tolerated, is effective against both the hemolymphatic and CNS stages of *T. brucei gambiense* infection. It does not have activity against *T. brucei rhodesiense*. Unfortunately, eflornithine is costly and supplies are limited. It is available in the United States from the CDC. It can be used alone, but eflornithine is often co-administered with nifurtimox for CNS *T. brucei gambiense* infection.

Melarsoprol is used for persons with CNS involvement due to *T. brucei rhodesiense* and *T. brucei gambiense* when eflornithine is not available or to treat relapses. Melarsoprol can result in severe toxicity, including life-threatening encephalopathic reactions.

Chagas Disease

Benznidazole or nifurtimox orally is used to treat *T. cruzi* infections (Chapter 318). Benznidazole has been the drug of choice in endemic areas of Latin America and nifurtimox in the United States. Both drugs, which are now commercially available in the United States, lower mortality and shorten the duration of acute Chagas disease. Treatment is recommended for persons with recent infection as well as asymptomatic children and adults through middle age with indeterminate-stage *T. cruzi* infection. Neither benznidazole nor nifurtimox can reverse the cardiac or gastrointestinal manifestations of chronic Chagas disease. Side effects are common with both drugs and increase in frequency and severity with age. Benznidazole is administered daily for 1 month and is associated with allergic dermatitis, peripheral neuropathy, insomnia, and gastrointestinal symptoms, including anorexia and weight loss. Nifurtimox is administered daily for 3 months and is associated with anorexia, nausea, vomiting, weight loss, headache, dizziness or vertigo, paresthesias, weakness, and polyneuropathy.

Leishmaniasis (Cutaneous, Mucosal, and Visceral)

Treatment of cutaneous leishmaniasis (Chapter 319) depends on the size, number, complexity, and location of skin lesions; their cosmetic impact; the infecting *Leishmania* species; and its propensity to cause mucosal disease.[10] Uncomplicated lesions acquired in Europe, Africa, and Asia, where mucosal involvement is rare, can be followed without therapy if they appear to be healing spontaneously. Lesion-directed treatment options include cryotherapy; heat therapy, which requires a specialized delivery system; or intralesional injection of stibogluconate sodium, which is not available in the United States. Topical therapy with direct application of paromomycin is another option. An ointment containing 15% paromomycin and 12% methylbenzethonium chloride in white paraffin developed in Israel has been used. A U.S. Army formulation of topical paromomycin also appears promising.

Parenteral or oral antileishmanial therapy is used for persons with complicated cutaneous leishmaniasis and for those who are or may be infected with *Leishmania braziliensis* or related New World species potentially associated with mucosal leishmaniasis.[A3] Miltefosine is FDA-approved for the oral treatment of cutaneous leishmaniasis due to *Leishmania braziliensis*. The efficacy with other *Leishmania* species varies. Liposomal amphotericin B and amphotericin B deoxycholate are effective, but more toxic, parenteral alternatives. Stibogluconate sodium and meglumine antimoniate are rarely used because of their toxicity, the requirement for parenteral administration, and increasing resistance. Fluconazole and other imidazole antifungals have activity against some *Leishmania* species.

Mucosal leishmaniasis (Chapter 319) is less responsive to treatment than cutaneous leishmaniasis, and relapses are common. Therapeutic options include liposomal amphotericin B, miltefosine, amphotericin B deoxycholate, stibogluconate sodium, or meglumine antimoniate.

Visceral leishmaniasis (Chapter 319) is a potentially fatal disease. The drug of choice is liposomal amphotericin B. Miltefosine and amphotericin B deoxycholate are alternatives for visceral leishmaniais[11] and post-kala-azar dermal leishmaniasis.[A4] Sodium stibogluconate and meglumine antimoniate are used in some geographic areas where resistance has not yet emerged.

Liposomal amphotericin B was the first drug approved by the FDA for treatment of visceral leishmaniasis (Chapter 319) in the United States. Liposomes deliver amphotericin to macrophages where leishmania reside. Liposomal amphotericin B is better tolerated than amphotericin B deoxycholate, which is an alternative. Other lipid-associated amphotericin B preparations appear to be effective, but they have been less extensively studied and are not FDA-approved for this indication.

Miltefosine, an alkylphospholipid and phosphocholine analog, initially developed as an antineoplastic drug, is FDA-approved for the treatment of visceral leishmaniasis and post-kala-azar cutaneous leishmaniasis due to *L. braziliensis*. A major advantage is oral administration. The pharmacokinetics are characterized by a long elimination half-life and extensive drug accumulation. The mechanism of action is uncertain, but miltefosine induces apoptosis-like changes in the parasite. Side effects are frequent but typically mild to moderate. Dose-dependent gastrointestinal toxicity can result in nausea, vomiting, and diarrhea, which tend to decrease with continued administration of the drug. Elevations in liver enzymes and creatinine are common but usually transient. Miltefosine is embryotoxic and is thus contraindicated during pregnancy. Contraceptive coverage is mandatory in women of childbearing years during and for 4 months after therapy. Relapses have been reported after the treatment of visceral leishmaniasis. They are frequent in persons with concurrent AIDS.

Stibogluconate sodium (available from the CDC) and meglumine antimoniate (still used in some areas of Latin America) are pentavalent antimony drugs that were used to treat visceral leishmaniasis in the past, but resistance is now common among *Leishmania donovani* isolates in India, adjacent countries, and some other areas of the world. Pentavalent antimony drugs require parenteral administration. Side effects increase with age and include gastrointestinal symptoms, pancreatitis, myalgias, headache, malaise, elevated liver enzyme levels, and occasionally bone marrow suppression. Nonspecific ST-T wave changes are common. Sudden death has been reported in older persons and in those receiving more than the recommended dose.

HELMINTHIC DISEASES

The treatment of helminthic diseases is discussed based on their taxonomy and the site of infection. A number of anthelminthic drugs are available. Albendazole, mebendazole, ivermectin, and pyrantel pamoate have replaced older anthelmintics that were more toxic, such as piperazine and thiabendazole, or less effective.[A5]

ANTHELMINTIC DRUGS

Albendazole

Albendazole is poorly soluble in water, but it is well absorbed when administered with a fatty meal. It undergoes rapid first-pass metabolism in the liver to albendazole sulfoxide, which has excellent anthelmintic activity. The serum half-life of albendazole sulfoxide is 8 to 9 hours. Elimination of albendazole sulfoxide and other metabolites is primarily through the kidney. Albendazole binds to tubulin in susceptible parasites, inhibits microtubule assembly, and decreases glucose absorption. It does not affect human tubulin. It also inhibits fumarate reductase in helminths. Concurrent administration of dexamethasone, which is frequently given to prevent cerebral edema in persons with neurocysticercosis, increases serum levels by approximately 50%. The CSF concentration of albendazole is approximately 40% that in serum.

Albendazole is generally well tolerated when given as a single dose for the treatment of intestinal roundworm infections, although gastrointestinal discomfort may develop, or patients may experience migration of adult *A. lumbricoides* from the nose or mouth or see them in their stool. Albendazole at higher doses and for longer duration (e.g., 15 mg/kg/day in two divided doses for 10 to 14 days) is used for persons with neurocysticercosis.[12] Corticosteroids are administered concurrently to reduce intracranial inflammation and increased intracranial pressure. Albendazole is contraindicated in persons with cysticerci in the eye or spinal cord. High-dose, prolonged therapy with albendazole, such as that recommended for echinococcal disease, can be complicated by alopecia, hepatitis, or bone marrow suppression, which is not always reversible after discontinuation of the drug. Albendazole is embryotoxic in animals and contraindicated during pregnancy.

Albendazole is used for inoperable *E. granulosus* and *Echinococcus multilocularis* disease and in persons in whom medical treatment is preferred for other reasons. Administered at a dose of 400 mg twice daily for adults, generally for 1 to 6 months, albendazole may cure approximately one third of uncomplicated *Echinococcus granulosus* liver cysts. Potentially fatal bone marrow suppression and hepatitis are concerns in persons receiving high-dose, prolonged albendazole therapy.

Albendazole is active against *A. lumbricoides*, the hookworms, and *T. trichiura*. Administered as a single 400-mg dose, it has been widely used in mass treatment programs in areas where these soil-transmitted roundworms are prevalent.[13] However, reinfection is common, and treatment is often repeated

at 3- to 4-month intervals. The CDC recommends presumptive treatment of immigrants from endemic regions with a single dose of albendazole before arrival in the United States. Daily doses of albendazole for 3 days are recommended for persons with heavy *T. trichiura* infection. Albendazole (400 mg twice daily for 7 days) is used as an alternative to ivermectin for the treatment of *Strongyloides stercoralis* infection. Albendazole is effective against *Enterobius vermicularis*, the pinworm, in a single dose that is repeated in 2 weeks. It can be used for cutaneous larva migrans, which is caused by migrating stages of *Ancylostoma braziliense* and other intestinal roundworms of animals. It is the drug of choice for trichinosis, and it has been used for the treatment of *Trichostrongylus* species and *Capillaria philippinensis*. There has been a massive increase in the cost of albendazole in the United States.

Mebendazole

Mebendazole is only slightly soluble in water and is relatively poorly absorbed from the gastrointestinal tract. This characteristic is advantageous for the treatment of intestinal parasites but limits its effectiveness against tissue-dwelling helminths. Absorbed drug is metabolized in the liver and excreted in urine. Mebendazole selectively binds to helminthic tubulin, blocks its assembly into microtubules, and inhibits glucose uptake. This leads to depletion of glycogen stores and ultimately death of the parasite. Mebendazole is relatively well tolerated in the doses used to treat intestinal helminths. Transient abdominal pain and diarrhea occur in a small number of recipients. Mebendazole is contraindicated during pregnancy.

Mebendazole (100 mg orally twice daily for 3 days) has a similar spectrum of activity as albendazole against *A. lumbricoides*, hookworms, and *T. trichiura*. In this regimen, it is more effective than a single dose of albendazole and is considered the treatment of choice for heavy *T. trichiura* infections. A single 500-mg dose of mebendazole has been used in mass treatment programs. Mebendazole is effective in treating pinworms when given at 100 mg orally in one dose followed by a second dose after 2 weeks. It is an alternative to albendazole for the treatment of trichinosis. Mebendazole is poorly absorbed and ineffective against *S. stercoralis*.

Ivermectin and Other Avermectins

Ivermectin is a macrocyclic lactone produced by *Streptomyces avermitilis*. It has a broad spectrum of activity against helminths and arthropods, including *Sarcoptes scabiei*, the cause of scabies. It is well absorbed after oral administration. Ivermectin is highly protein bound, has a serum half-life of 12 hours, and accumulates in adipose tissue and the liver. It is subject to enterohepatic recirculation and ultimately eliminated in stool. Ivermectin activates the opening of gated chloride channels in susceptible helminths and arthropods. The result is an influx of chloride ions and paralysis of the pharyngeal pumping mechanism of helminths. Ivermectin is generally well tolerated in humans, although inflammatory reactions can develop in response to antigens released from dying parasites.

Ivermectin at an oral dose of 200 µg/kg daily for 2 days is considered the treatment of choice for uncomplicated *S. stercoralis*. In immunocompromised persons with hyperinfection, daily doses are given until stool and sputum exams are negative for larvae for 2 weeks. It is also effective against cutaneous larva migrans and *A. lumbricoides* but not hookworms. It is an alternative to mebendazole for the treatment of *T. trichiura*.

Ivermectin is the treatment of choice for onchocerciasis. It is administered as a single dose of 150 µg/kg. It does not kill adult *Onchocerca volvulus*, but it decreases ova production and reduces microfilariae in the skin and eyes. Retreatment is usually necessary at 6- to 12-month intervals until the patient is free of symptoms. For *Onchocerca volvulus*, biannual treatment leads to substantial reductions in community infection rates after four or five rounds of therapy. Ivermectin has activity against the microfilariae of *W. bancrofti* and *Brugia* species, the agents of lymphatic filariasis, but it does not kill adult worms and is not recommended for definitive treatment of these organisms. Ivermectin is used widely in mass drug administration programs for reducing the transmission of lymphatic filariasis and onchocerciasis, and it has the added benefit of reducing the transmission of scabies.[A6] Ivermectin should not be given to persons with heavy concurrent *Loa loa* infections because it kills *Loa loa* microfilaria rapidly and can result in encephalopathy.

Moxidectin, an avermectin compound similar to ivermectin, has long been used in veterinary medicine and is now approved for treatment of onchocerciasis. Single-dose moxidectin provides longer clearance of *O. volvulus* skin microfilariae than single-dose ivermectin, an effect that is likely related to the prolonged (about 23 days) half-life of moxidectin.[A7] Moxidectin is not yet approved for use in children <12 years of age, and data are insufficient regarding its safety in pregnant or breast-feeding women.

Pyrantel Pamoate and Oxantel Pamoate

Pyrantel pamoate is a relatively safe, poorly absorbed over-the-counter drug with activity against *A. lumbricoides*, hookworms, and pinworm, but it is not effective against *T. trichiura* or *S. stercoralis*. When used for pinworm infection, it is administered as an oral suspension at a dose of 11 mg/kg (to a maximum of 1 g), which is repeated after 2 weeks. A structural analogue, oxantel pamoate, has increased activity against *T. trichiura* but is not available in the United States. Three-drug therapy with pyrantel pamoate, oxantel pamoate, and albendazole is superior to two-drug combinations for hookworm and provides high cure rates for *T. trichiura* and *A. lumbricoides*.[A8]

Praziquantel

Praziquantel is well absorbed after oral administration. It undergoes extensive first-pass metabolism, and the metabolites, which are inactive, are excreted in urine. Praziquantel is approximately 80% protein bound, with a serum half-life of 4 to 6 hours. It is rapidly taken up by susceptible cestodes and trematodes. In the case of schistosomes, praziquantel damages the tegument, which results in intense vacuolation and increased permeability to calcium. Adult schistosomes are paralyzed and translocated to the liver through the portal circulation. Sequestered antigens are exposed on their surface, permitting binding of antibodies and phagocytes resulting in immune destruction.

Praziquantel has a broad spectrum of activity against tapeworms (Chapter 325) and flukes. It is the drug of choice for adult tapeworms in the human intestinal tract. It is effective against *Taenia solium* (pork tapeworm), *Taenia saginata* (beef tapeworm), *Taenia asiatica* (Asian tapeworm), *Diphyllobothrium latum* (fish), and *Hymenolepis nana* (dwarf tapeworm) when administered as a single dose. Praziquantel (50/mg/kg/day for 10 to 14 days) is used in combination with or as an alternative to albendazole for the treatment of neurocysticercosis. The concurrent administration of corticosteroids, which are necessary to decrease inflammation and edema in the brain, reduces the serum concentration of praziquantel. The concentration in CSF is approximately 15 to 20% that of serum.

Praziquantel is frequently associated with mild, transient side effects, including headaches, lassitude, dizziness, nausea, vomiting, and abdominal discomfort, but they are seldom severe enough to interrupt therapy. Untoward reactions attributed to release of parasite antigens have been reported in patients treated for schistosomiasis and pulmonary paragonimiasis. Increased intracranial pressure resulting from release of cysticercal antigens is a potentially life-threatening consequence in patients receiving praziquantel for neurocysticercosis. Corticosteroids should be administered concurrently. Praziquantel is contraindicated in persons with cysticerci in the eye or spinal cord.

Praziquantel is the drug of choice for the treatment of all forms of schistosomiasis (Chapter 326), as well as intestinal, lung, and liver flukes (Chapter 326), with the exception of *Fasciola hepatica*. For schistosomiasis, two or three doses of praziquantel are given in 1 day depending on the species. Oxamniquine is an alternative for *Schistosoma mansoni*, but it is more toxic and less effective.

Diethylcarbamazine

Diethylcarbamazine, a piperazine derivative, is well-absorbed orally and has a half-life of 8 hours. The parent drug and its metabolites are excreted through the kidney. Although the mechanism of action is uncertain, the piperazine moiety may result in paralysis of sensitive helminths. Diethylcarbamazine also alters the surface membranes of susceptible microfilariae, thereby resulting in destruction by the host's immune system. Side effects include those caused by the drug and those that result from release of the parasite antigens and lipopolysaccharide from filaria-harbored, endosymbiotic *Wolbachia*. Adverse effects include nausea, vomiting, anorexia, headache, malaise, weakness, arthralgias, and rarely, acute psychotic reactions. In patients with lymphatic filariasis, localized swelling or nodules may develop along the lymphatics during treatment, and transient lymphedema or hydrocele may develop.

Diethylcarbamazine is the drug of choice for the treatment of lymphatic filarial infections (Chapter 327) caused by *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*, as well as for tropical pulmonary eosinophilia. It promotes the host's killing of microfilariae of these species and also damages or kills adult worms. Inflammatory side effects are common. They are due in part to the release of lipopolysaccharide from endosymbiotic *Wolbachia* bacteria within dying filaria. *Wolbachia* are necessary for filarial development and are a potential drug target. Long-term therapy with doxycycline results in their

elimination and has been used for therapy. Diethylcarbamazine is also used for *Loa loa* infections in persons with acceptably low levels of microfilaremia (<8000/mL). Encephalopathy may result from treatment of those with more. In that case, apheresis or treatment with albendazole is used first to reduce the number of microfilariae. Diethylcarbamazine should not be used for onchocerciasis. It kills the microfilariae of *O. volvulus* rapidly, and the release of parasite and *Wolbachia* antigens can result in severe ocular and systemic inflammatory responses. The latter, known as the Mazzotti reaction, can be life-threatening and is characterized by fever, urticaria, lymphadenopathy, tachycardia, hypotension, arthralgias, peripheral edema, and abdominal pain. Diethylcarbamazine has also been used prophylactically to prevent loiasis.

Other Drugs

Niclosamide, which is not absorbed, is an effective alternative for the treatment of *T. saginata* and *D. latum*. It also kills adult *T. solium*, but disintegration of the worm and release of viable ova into the intestinal lumen raise the theoretical possibility of autoinfection. Nitazoxanide also has activity against *T. saginata* and potentially other tapeworm species. In the case of *H. nana*, a dose of nitazoxanide 500 mg twice daily for 3 days provides an alternative to praziquantel.

316 MALARIA

PHILIP J. ROSENTHAL AND MOSES R. KAMYA

DEFINITION

Malaria is caused by infection with protozoan parasites of the genus *Plasmodium*, all of which are transmitted by bites of infected anopheline mosquitoes.[1] Malaria is typically characterized by an acute febrile illness, with parasites infecting large numbers of erythrocytes, and classically entails recurrent episodes of fever and chills. Malaria causes hundreds of millions of illnesses each year throughout most of the tropics. Severe disease can occur, primarily with *Plasmodium falciparum* infection, with the acute development of serious organ dysfunction. Chronic and repeated infection leads to severe anemia.

The Pathogen

P. falciparum, which is responsible for most episodes of severe malaria, is endemic in most malarious areas and is by far the predominant species in Africa. *Plasmodium vivax* is about as common as *P. falciparum*, except in Africa, but it causes severe disease much less commonly.[2] *Plasmodium ovale* and *Plasmodium malariae* are much less common causes of disease and generally do not cause severe illness. *Plasmodium knowlesi*, which is a parasite of macaque monkeys, is a fairly common zoonosis in parts of Southeast Asia and has been responsible for malarial illnesses, including severe disease, in individuals exposed to macaque-biting vectors in forested areas. Other zoonotic plasmodia, including *Plasmodium cynomolgi* in southeast Asia and *Plasmodium simium* and *Plasmodium brasilianum* (which may be zoonotic forms of *P. vivax* and *P. malariae*, respectively, in Brazil), occasionally cause human disease.

EPIDEMIOLOGY

Malaria in Endemic Countries

Malaria, which is the most important parasitic disease of humans, is endemic in most of the tropics, including many parts of Africa, South and Central America, the Middle East, the Indian subcontinent, Southeast Asia, and Oceania. Transmission, morbidity, and mortality are greatest in Africa, where infection with *P. falciparum* predominates. In most other endemic areas, disease caused by both *P. falciparum* and *P. vivax* is common. In highly endemic areas, the group at greatest risk is young children, who experience the most episodes of disease and the most deaths. A second high-risk group is pregnant women, with high risks of maternal and fetal morbidity from *P. falciparum* malaria, including many deaths secondary to low birthweight. In highly endemic areas, in addition to extensive mortality, malaria exerts a massive toll through its adverse effects on child development; contributions to school and work absenteeism; and, overall, billions of dollars in lost income among the poorest citizens of the poorest countries of the world. In areas of developing countries with lower levels of malaria transmission, malaria can be epidemic, with intermittent increases in transmission that cause major morbidity in relatively nonimmune populations. Increased control activities worldwide reduced malaria deaths by almost 60% from 2000 to 2015, but morbidity and mortality appear to have stabilized since 2015.[3] Currently, malaria is estimated to cause nearly 250 million clinical cases and over 600,000 deaths annually worldwide.[4]

Malaria in Travelers

Malaria is also common when travelers of any age travel from nonendemic areas to the tropics, with symptoms sometimes not manifesting until many months after travel (Chapter 265). Malaria is the most common documented cause of febrile illness in travelers returning from the tropics to developed countries. Malaria is also occasionally transmitted in areas considered nonendemic, including the United States, when imported parasites are transmitted by local anopheline mosquitoes, by blood products, or by congenital spread.

Malaria Transmission

Malaria is transmitted by multiple species of mosquitoes of the genus *Anopheles*, which vary in geographic distribution, ecologic preferences, and susceptibility to mosquito control measures. Anopheline mosquitoes bite at night, so personal mosquito control measures focus on avoidance of mosquito bites during sleep. Levels of malaria transmission in endemic areas vary greatly, from areas where residents experience only rare infectious bites to regions of Africa where individuals may receive hundreds of infectious bites each year.

PATHOBIOLOGY

Parasite Life Cycle

Malaria is transmitted by the bite of infected female anopheline mosquitoes. During feeding, mosquitoes inject sporozoites, which circulate to the liver and infect hepatocytes, thereby causing asymptomatic liver infection (Fig. 316-1). Merozoites are subsequently released from the liver, and they rapidly infect erythrocytes to begin the asexual erythrocytic stage of infection that is responsible for human disease. Multiple rounds of erythrocytic development, with production of merozoites that invade additional erythrocytes, lead to large numbers of circulating parasites and clinical illness. Each erythrocytic cycle lasts approximately 24 hours for *P. knowlesi*; 48 hours for

ABSTRACT

Malaria, which is the most important parasitic disease of humans and one of the most important infectious disease problems in the world, causes hundreds of millions of illnesses and hundreds of thousands of deaths each year. Progress toward the elimination of malaria is evident in many areas, but the disease remains an enormous problem in much of the tropics, and in particular in Africa. Malaria commonly presents as an uncomplicated febrile illness, but it can progress to severe disease. Treatment of malaria with older agents is challenged by drug resistance, but artemisinin-based combination therapy is generally highly effective, except in areas of southeast Asia, where resistance to these therapies is a growing problem. The control of malaria relies on control of mosquito vectors, prompt treatment of infections, and use of drugs to prevent infection. Multiple approaches to malaria vaccines are under study.

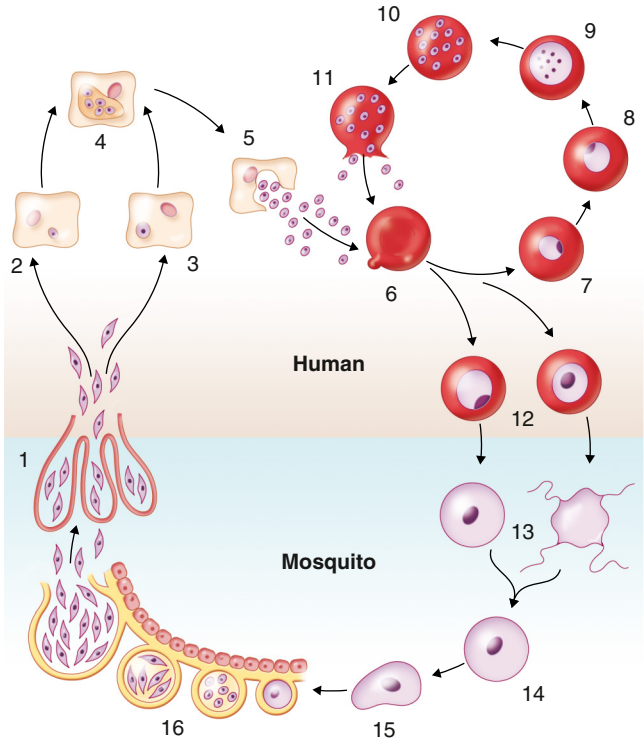

FIGURE 316-1. Life cycle of the malaria parasite. The *upper* and *lower halves* of the diagram indicate the human and anopheline mosquito parts of the cycle, respectively. Sporozoites from the salivary gland of a female *Anopheles* mosquito are injected under the skin (1). They then travel through the blood stream to the liver (2) and mature within hepatocytes to become tissue schizonts (4). Up to 30,000 parasites are then released into the blood stream as merozoites (5) and produce symptomatic infection as they invade and destroy red blood cells. However, in *Plasmodium vivax* and *Plasmodium ovale* infection, some parasites remain dormant in the liver as hypnozoites (3), which can later develop to tissue schizonts and merozoites, leading to relapse. Within the blood stream, merozoites (5) invade erythrocytes (6) and mature to the ring (7, 8), trophozoite (9), and schizont (10) asexual stages. Mature schizonts lyse their host erythrocytes and release the next generation of merozoites (11), which invade previously uninfected cells. Some erythrocytic parasites differentiate to sexual forms (male and female gametocytes) (12). When taken up by a mosquito, the gametocytes mature to male and female gametes (13), fuse to form zygotes (14), and then develop into ookinetes that invade the gut of the mosquito (15) and develop into oocysts (16). Mature oocysts produce sporozoites, which migrate to the salivary gland of the mosquito (1) to allow another human infection. (From Krogstad DJ: Blood and tissue protozoa. In: Schaechter M, Medoff G, Eisenstein BI, eds. *Mechanisms of Microbial Diseases*. 2nd ed. Baltimore: Williams & Wilkins; 1993:600.)

P. falciparum, *P. vivax*, and *P. ovale;* and 72 hours for *P. malariae*. Some erythrocytic parasites also develop into sexual gametocytes, which are taken up by mosquitoes. In the mosquito, gametocytes mature to gametes, and after fusion of male and female gametes to produce zygotes, parasites develop into ookinetes, oocysts, and then salivary gland sporozoites that are infectious for humans, thereby allowing completion of the life cycle and infection of others. *P. vivax* and *P. ovale* also cause a chronic liver infection, in which hypnozoites persist in hepatocytes in a dormant state not eradicated by most therapies for acute disease and subsequently can progress to erythrocytic infection and a relapse of clinical illness.

Pathogenic Features of Malaria Parasites

The most common clinical feature of malaria is fever. Fever coincides with rupture of large numbers of schizont-infected erythrocytes at the completion of the erythrocytic cycle and with high circulating levels of tumor necrosis factor (TNF). Severe falciparum malaria is associated with very high levels of TNF and other inflammatory cytokines, but the specific roles of cytokines in pathogenesis are not well understood. *P. falciparum* infects erythrocytes of all ages, so it is capable of routinely causing high parasitemias, with infection of more than 1% of erythrocytes and more than 10^5 infected erythrocytes per microliter of blood. Non–*P. falciparum* parasites infect smaller numbers of erythrocytes, thereby limiting the extent of infection and morbidity. Non–*P. falciparum* parasites are more likely to cause highly synchronous infections, so untreated infected patients can have regular cycles of fever every 48 (*P. vivax* and *P. ovale*) or 72 (*P. malariae*) hours, often with minimal symptoms between fever episodes.

The contribution of parasitic virulence determinants to the severity of malaria is poorly understood. A key biologic feature of *P. falciparum* infection is the ability of parasites to mediate the adherence of infected erythrocytes to a number of ligands on endothelial cells. By this mechanism, erythrocytes infected with the more mature stages of erythrocytic parasites do not circulate but rather adhere within small blood vessels in the brain and other organs. This phenomenon, termed cytoadherence, allows parasites to avoid passing through the spleen, where abnormal erythrocytes would be cleared. Cytoadherence is also likely to play a major role in mediating severe manifestations of *P. falciparum* malaria, with local inflammatory changes mediated by large numbers of adherent parasites leading to organ dysfunction. Pregnancy selects for a subset of *P. falciparum* strains that specifically bind to ligands in the placenta.

P. falciparum parasites use antigenic variation to evade the host immune response. The principal protein that mediates the cytoadherence of infected erythrocytes to endothelial cells, *P. falciparum* erythrocyte membrane protein-1 (PfEMP-1), is transported to the erythrocyte surface and is a target of host immune responses that limit infection. The PfEMP-1 family comprises about 60 proteins, but only one PfEMP-1 variant is expressed on the surface of an infected erythrocyte at a time. During the course of an infection, parasites frequently vary the expression of PfEMP-1s to stymie host responses. This factor and the high variability in sequence of many PfEMP-1 molecules present a broad repertoire of antigens and probably help explain the slow acquisition of protective antimalarial immunity. Antigenic variation and other aspects of immunologic diversity are not clearly understood for non–*P. falciparum* malaria parasites, but each species appears capable of repeated infections.

Host Immunity and Genetics

The nature of human immune responses to malaria is not well characterized, but protective responses require multiple infections and apparently humoral and cell-mediated responses.[5] Where *P. falciparum* malaria is common, disease occurs primarily in children. After some protection during the first few months of life, probably because of protective effects of maternal antiplasmodial antibodies and fetal hemoglobin, young children are infected frequently, experience repeated febrile malaria illnesses, and are at high risk of severe disease. With repeated episodes of malaria, children develop partial immunity. Immunity develops gradually, with some protection against severe malaria after only a few infections, increasing protection against symptomatic illness, and eventually strong protection against infection. However, antimalarial immunity is not complete; malaria can occur in individuals of any age. In addition, immunity requires boosting by repeated infections, so adults are at increased risk of disease if they return to a highly endemic site after an extended stay in a nonendemic area.

A number of human genetic polymorphisms offer protection against malaria. The best characterized is sickle hemoglobin (Chapter 149). Hemoglobin S heterozygotes are partially protected against severe *P. falciparum* malaria, leading to a balanced polymorphism in which the survival advantage of the polymorphism allows persistence of sickle cell disease in homozygotes. Other erythrocyte polymorphisms that also are likely to offer protection against malaria include hemoglobin C and E, thalassemias (Chapter 148), glucose-6-phosphate dehydrogenase deficiency (Chapter 147), and ovalocytosis (Chapter 147). The Duffy antigen, an erythrocyte chemokine receptor of uncertain function, is the principal receptor on human erythrocytes for attachment and subsequent invasion of *P. vivax*. Most Africans lack the erythrocyte Duffy antigen, explaining the uncommon prevalence of *P. vivax* in most of Africa.

CLINICAL MANIFESTATIONS

In highly endemic areas, young children experience frequent episodes of malaria, older children are frequently infected but less commonly symptomatic, and adults are uncommonly parasitemic or symptomatic; nevertheless, some risk of severe malaria remains at all ages. Infection can be severe in adults who are from nonendemic areas or who have lived away from endemic areas for an extended period of time.

Uncomplicated Malaria

Most malarial episodes, even with *P. falciparum* infection, are uncomplicated. The incubation period after an infectious bite is usually 10 to 14 days for *P. falciparum* and about 2 weeks for other species, but it can be much longer, especially in non–*P. falciparum* malaria and in individuals with prior immunity. The hallmark of malaria is fever, often with a nonspecific influenza-like

prodrome including headache and fatigue followed by a classic malarial paroxysm including chills, high fever, and then sweats. Patients may be remarkably well between febrile episodes. Fevers are typically irregular early in the illness, but without therapy, they may become regular, with 48-hour (*P. vivax* and *P. ovale*) or 72-hour (*P. malariae*) cycles, especially with non–*P. falciparum* disease. Headache, malaise, myalgias, arthralgias, rigors, confusion, cough, chest pain, abdominal pain, anorexia, nausea, vomiting, and diarrhea are common. Seizures are often simple febrile convulsions, especially in young children, but they also may represent evidence of severe neurologic disease.

Physical findings may be absent or include signs of anemia, jaundice, splenomegaly, and mild hepatomegaly. Rash and lymphadenopathy are not typical in malaria and thus are suggestive of another cause of fever.

Laboratory studies commonly show anemia, thrombocytopenia, and liver and renal function abnormalities. Anemia is caused by destruction of infected and uninfected erythrocytes, decreased hematopoiesis, and bleeding. In many endemic areas, most asymptomatic young children who have chronic *P. falciparum* infection have chronic anemia, sometimes exacerbated by nutritional deficits and intestinal roundworm infections.

Plasmodial parasites other than *P. falciparum* do not cause cytoadherence of infected erythrocytes, infect lower numbers of erythrocytes, and are much less commonly responsible for complicated and severe disease. However, *P. vivax* can cause severe disease, in particular respiratory compromise. *P. vivax* is also particularly prone to cause splenic rupture, although this complication can be seen with all malarial species. *P. malariae* most commonly causes a mild febrile illness, but chronic or repeated infection has been associated with an immune complex–mediated glomerulonephritis with nephrotic syndrome (Chapter 107). *P. knowlesi* can cause severe illness, including deaths. The short (24-hour) erythrocytic cycle of *P. knowlesi* may partly explain the propensity of this zoonotic parasite to cause severe illness.

Severe *P. falciparum* Malaria

Severe malaria can present with signs of severe illness or organ dysfunction (including prostration, impaired consciousness, convulsions, respiratory distress, shock, acidosis, severe anemia, excessive bleeding, hypoglycemia, jaundice, hemoglobinuria, and renal impairment) or a high parasite load (generally peripheral parasitemia >5% or >200,000 parasites/μL).[6] *P. falciparum* malaria can progress to cerebral malaria, including coma; noncardiogenic pulmonary edema, including severe respiratory compromise; and renal failure, severe anemia, acidosis, hypoglycemia, and other syndromes of organ dysfunction.

Cerebral malaria, the most common severe complication in children, is generally defined as altered consciousness in the setting of *P. falciparum* malaria. Seizures are common, and deep coma, abnormal posturing, focal neurologic findings, and abnormal respiratory patterns can be seen.

Severe anemia is a common presentation, particularly in young children. Respiratory failure is caused by noncardiogenic pulmonary edema and is more common in adults than in children. Acute renal failure is also more common in adults and generally due to hypoperfusion and acute tubular necrosis. Blackwater fever, including intravascular hemolysis and hemoglobinuria, has an uncertain etiology but can be caused by quinine; hepatic dysfunction, including jaundice, can be seen. Jaundice also may be caused by hemolysis. Splenic enlargement is common, and splenic rupture can occur. Hypoglycemia is common because of glucose consumption by parasites, increased demand, impaired gluconeogenesis, and quinine-induced insulin secretion. Metabolic acidosis, particularly lactic acidosis, is common, and electrolyte derangements can be seen. Coagulopathy, caused by consumption of clotting factors, and marked thrombocytopenia, caused by increased platelet turnover, can lead to significant bleeding. Bacterial infection and sepsis can coexist with malaria.

Pregnant women in endemic areas, in particular women in their first pregnancy who lack antibodies specific for placenta-binding parasites, are at high risk of morbidity, including anemia from high parasitic loads in the placenta. Poor fetal outcomes, including intrauterine growth restriction, spontaneous abortion, and low birthweight, are common.

Complications of Non–*P. falciparum* Malaria

The large majority of infections with non–*P. falciparum* parasites are uncomplicated both in endemic areas and in nonimmune travelers. Nonetheless, *P. vivax* infection is common in many areas, and it is responsible for about a quarter of children hospitalized with severe malaria in Asia and Oceania. Important features of severe *P. vivax* malaria include severe anemia and respiratory distress. All malarias, but in particular *P. vivax* infection, can be complicated by splenic rupture.

Chronic malaria infections can be complicated by hyperreactive malarial splenomegaly, with massive splenomegaly and findings of hypersplenism. Chronic infections can also lead to the nephrotic syndrome (Chapter 107), particularly with *P. malariae* infection.

DIAGNOSIS

Clinical Features

In individuals with febrile illness and malaria risk, it is essential to make a diagnosis promptly and important to distinguish the different species that infect humans because management differs according to the infecting species. Malaria is the most common cause of febrile illness in many areas that have limited diagnostic capabilities, so it is frequently diagnosed based only on presentation with a febrile illness. However, formal diagnosis is preferred. In travelers returning from endemic areas with fever, the travel history can aid in the diagnosis (Chapter 265). Malaria is most likely in individuals who failed to use measures to prevent infection and in travelers to the most highly endemic areas, such as rural sub-Saharan Africa. *P. falciparum* malaria generally has a fairly short incubation period in nonimmune individuals, so it presents within 1 to 2 months of return in more than 90% of infected travelers.[7] Infection with the other malarial species can present a number of months and uncommonly more than 1 year after exposure.

Blood Smears

The gold standard means of diagnosis in malaria-endemic areas is by thick blood smear.[8] In this procedure, one drop of blood is dried on a slide and parasites are stained with Giemsa. Parasites are easily identified by trained microscopists, and the density of parasites can be estimated on the basis of counts relative to those of leukocytes. However, thick blood smears do not allow identification of erythrocytic morphology, which is helpful in species diagnosis, and are difficult for individuals with limited training. Giemsa-stained thin blood smears offer an improved means of characterizing parasitic morphology, but the process is more time-consuming than for thick smears. Thus, thick smears are the standard means of diagnosis in highly endemic areas, whereas thin smears are preferred where malaria is uncommon and where laboratory personnel have ample time to examine multiple microscopic fields.

It is important to distinguish infecting species of malaria parasites. In *P. falciparum* infection, generally only ring-form asexual parasites are seen. Trophozoites of *P. vivax* and *P. ovale* are present in enlarged (and ovoid in the case of *P. ovale*) erythrocytes that contain inclusions known as Schüffner dots. Intraerythrocytic *P. malariae* and *P. knowlesi* trophozoites are often elongate in shape. Sexual stage gametocytes (which have a characteristic oblong shape in *P. falciparum*) are also seen on blood smears.

Antigen Detection

Multiple simple antigen detection tests incorporate colorimetric detection of one or two antigens in an assay that requires limited training and only a few minutes. The most used assays in Africa use histidine-rich protein-2 (HRP2), a protein that is abundant and long-lived but expressed only by *P. falciparum*. Other assays identify plasmodial lactate dehydrogenase and aldolase, which are produced by all human malarial species. Some tests use two antigens to separately identify *P. falciparum* and all-species plasmodial infection. Rapid diagnostic tests have become a standard component of many malaria control programs. One test is approved in the United States. However, there is increasing evidence of *P. falciparum* lacking HRP2 in some areas, in particular in parts of South America and the Horn of Africa, thereby leading to concern that HRP2-based diagnostic tests may miss some cases of falciparum malaria, and that diagnostic approaches may need to be changed.[9]

Other Diagnostic Tests

Serologic tests can identify prior malaria infection, but responses develop slowly and persist for an extended period, so these tests have limited value for acute diagnosis. Malaria parasites can be identified with molecular amplification assays using primers encoding genus- and species-specific sequences. These tests are highly sensitive and convenient for research purposes because they can be conducted on DNA extracted from blood spotted onto filter paper in field settings. Quantitative polymerase chain reaction assays are most sensitive, but loop-mediated isothermal amplification and related assays are highly sensitive and more practical for many field settings. Molecular assays are not practical for routine diagnosis, however, because of the time required, the uncertain significance of a positive result in endemic areas where low-level parasitemia may be clinically insignificant, cost, and logistical requirements.

Human Immunodeficiency Virus (HIV) Coinfection

HIV infection appears to disrupt the acquired immune response to malaria and thereby increases the incidence and severity of malaria. Acute malaria elevates the HIV viral load and so may increase the risk of HIV transmission. HIV infection also may be associated with reduced efficacy of antimalarial treatment, especially in the setting of severe immune suppression. Therapies for each infection may have an impact on the other, thereby leading to unanticipated effects on drug efficacy or toxicity. For example, daily prophylactic trimethoprim–sulfamethoxazole in HIV-infected patients with low CD4 counts offers partial protection against malaria.

TREATMENT

Prompt treatment is key for optimal outcomes, especially for *P. falciparum*. With severe illness, treatment should be started as soon as a presumptive diagnosis is made. Most treatments do not eradicate gametocytes, so persistence of these forms for a few weeks is not a sign of treatment failure.

Antimalarial Drug Treatment

The treatment of falciparum malaria is challenging because of evolving patterns of drug resistance. Artemisinin-based combination therapy is recommended in nearly all countries with endemic *P. falciparum* malaria (Table 316-1).[10] Non–*P. falciparum* malaria is still generally treated with chloroquine, although chloroquine resistance is increasing in *P. vivax;* resistant vivax malaria can be treated with other drugs used to treat falciparum malaria.

Artemisinins

Artemisinin, the active component of an herbal medicine from China, and a number of its analogues offer rapid elimination of circulating malaria parasites and activity against gametocytes to limit disease transmission. These drugs are short-acting, thereby leading to frequent recrudescences of infection after short-course monotherapy. For this reason and to limit selection of resistance, artemisinins are now used in combination with longer-acting drugs to treat malaria in 3-day regimens. These combinations have become the standard therapies for *P. falciparum* malaria (Table 316-2). Leading regimens are fixed-dose combinations of artemether–lumefantrine (Coartem; the only artemisinin-based combination therapy approved in the United States), artesunate–amodiaquine, artesunate–mefloquine, dihydroartemisinin–piperaquine, and artesunate-pyronaridine. All these regimens have demonstrated excellent treatment efficacy in Africa,[A1,A2] including in children[A3] and pregnant women[A4]; different regimens have had optimal efficacy in different regions. Artemisinin-based combination therapies also have shown excellent efficacy for the treatment of vivax malaria.[A5] Other artemisinin-based combination therapies that are not currently recommended by the World Health Organization (WHO) but are available for the treatment of malaria in some countries and have also shown good efficacy include artero-lane–piperaquine,[A6] artemisinin–piperaquine,[A7] and artemisinin–naphthoquine. Resistance of *P. falciparum* to artemisinins, manifesting as a prolonged time to parasite clearance after therapy, has emerged in Southeast Asia in association with mutations in the *kelch13* gene.[11] Of great concern, treatment efficacies of artemisinin-based combination therapies have waned in parts of Southeast Asia, most notably for dihydroartemisinin–piperaquine, with resistance to both components of the regimen leading to high clinical failure rates. In Africa, parasites with genetic polymorphisms suggestive of similar resistance phenotypes have recently emerged in Rwanda[12] and Uganda[13]; these polymorphisms have been accompanied by delayed clearance of malaria parasites, but it is not yet clear if they are associated with poorer efficacy for artemisinin combinations.

Artemisinins also have a key role for the treatment of severe malaria. IV artesunate is superior to quinine for the treatment of severe malaria, and it is the first-line therapy for severe malaria in the United States. For settings with limited infrastructure, intramuscular artemether and intramuscular or intrarectal artesunate[A8] have also shown excellent efficacy. Artemisinins are generally very well tolerated, with minimal toxicity, although delayed hemolysis can occur after therapy, in particular with IV artesunate.

Chloroquine and Other Aminoquinolines

Chloroquine, which remains the treatment of choice for non–*P. falciparum* malaria and *P. falciparum* malaria in the few areas without resistance (Central America and the Caribbean), is generally rapidly effective and well tolerated. For *P. vivax* and *P. ovale* infections, primaquine or tafenoquine also must be given to eradicate dormant liver forms and thereby prevent subsequent relapse. Chloroquine remains effective as weekly chemoprophylaxis to prevent malaria in areas without resistance.

Amodiaquine and piperaquine probably share mechanisms of action with chloroquine, but they are routinely active against chloroquine-resistant parasites because of increased potency compared with chloroquine and some differences in mechanisms of resistance; each is now a component of a leading artemisinin-based combination therapy (see Table 316-2). Amodiaquine is somewhat less well tolerated than other aminoquinolines. It is generally safe for short-term use but can cause rare serious hepatic and bone marrow toxicity,

TABLE 316-1 TREATMENT OF MALARIA*

CHLOROQUINE-RESISTANT PLASMODIUM FALCIPARUM, RESISTANT PLASMODIUM VIVAX, OR SPECIES UNIDENTIFIED	
ORAL TREATMENT OF UNCOMPLICATED DISEASE	
Coartem (artemether 20 mg, lumefantrine 120 mg)	4 tablets orally twice daily for 3 days
or	
Malarone (atovaquone 250 mg, proguanil 100 mg)	4 tablets daily for 3 days
or	
Quinine	650 mg quinine sulfate 3 times daily for 3-7 days
plus	
Doxycycline	100 mg twice daily for 7 days
or plus	
Clindamycin	600 mg twice daily for 7 days
or	
Mefloquine	750 mg followed by 500 mg in 6-8 hours; also can be given as a single 1250-mg dose, although this is less well tolerated than the divided dose
COMPLICATED *P. FALCIPARUM* MALARIA OR UNABLE TO TOLERATE ORAL MEDICATIONS†	
IV artesunate	2.4 mg/kg every 12 hr on day 1; then daily for 2 additional days
or	
IV quinine dihydrochloride§,‖	20 mg/kg over 4 hr; then 10 mg/kg every 8 hr
or	
IM artemether‖	3.2 mg/kg IM; then 1.6 mg/kg/day
CHLOROQUINE-SUSCEPTIBLE *P. FALCIPARUM* AND OTHER SPECIES	
Chloroquine phosphate	1 g, followed by 500 mg at 6, 24, and 48 hr *or* 1 g at 0 and 24 hr; then 0.5 g at 48 hr
plus (for *P. vivax* and *P. ovale* only)	
Primaquine¶	30-mg base (52.6 mg primaquine phosphate) daily for 14 days
or	
Tafenoquine¶	300 mg single dose

*Dosages are for adults.
†IV regimens should be given until the patient can tolerate oral agents and then followed by a course of oral therapy (doxycycline, clindamycin, or full treatment courses of other drugs, as listed) when patients can tolerate this.
§Cardiac monitoring should be in place during IV administration of quinine.
‖Not available in the United States.
¶Use primaquine or tafenoquine only after demonstrating normal levels of glucose-6-phosphate dehydrogenase.
IM = intramuscular; IV = intravenous.

TABLE 316-2 RECOMMENDATIONS FOR THE TREATMENT OF *PLASMODIUM FALCIPARUM* MALARIA IN DEVELOPING COUNTRIES*

REGIMEN	NOTES
Artemether–lumefantrine (Coartem, Riamet)	First-line therapy in many countries; FDA approved
Artesunate–amodiaquine (ASAQ)	First-line therapy in some African countries
Artesunate–mefloquine	Standard therapy in parts of Southeast Asia
Dihydroartemisinin–piperaquine	Limited by resistance in Southeast Asia, but highly effective elsewhere
Artesunate-pyronaridine	Highly efficacious newer regimen

*Recommendations modified from World Health Organization. Guidelines for malaria, 2021 (https://www.who.int/teams/global-malaria-programme/guidelines-for-malaria).
FDA = U.S. Food and Drug Administration.

especially with chronic use, and so it is not recommended for chemoprophylaxis. The artemisinin-based combination therapy dihydroartemisinin-piperaquine has shown excellent efficacy in most regions, but frequent failures, mediated by resistance to both components of the regimen, are seen in parts of Southeast Asia.

Mefloquine, Lumefantrine, and Pyronaridine

Mefloquine offers effective therapy and chemoprophylaxis for most chloroquine-resistant strains of *P. falciparum* as well as for other species. Resistance to mefloquine is uncommon but has been seen in parts of Southeast Asia, with failures of the artemisinin-based combination therapy artesunate-mefloquine. Mefloquine is one of three drugs recommended for chemoprophylaxis against *P. falciparum* by the Centers for Disease Control and Prevention (CDC). Tolerability of chemoprophylactic and especially treatment doses of mefloquine is often limited by neurologic and gastrointestinal toxicity. Lumefantrine is used only in combination and offers effective therapy with artemether as Coartem, the most widely used artemisinin-based combination therapy used to treat falciparum malaria. The artemisinin-based combination therapy artesunate-pyronaridine offers another effective treatment for falciparum malaria. Importantly, there is no clear evidence of *P. falciparum* resistance to either lumefantrine or pyronaridine.

Quinine

Quinine offers rapid action against all species with limited known resistance except in Southeast Asia, where failures against *P. falciparum* malaria are fairly common. Quinine can be used to treat uncomplicated malaria, but gastrointestinal and other nonspecific toxicities lead to difficulty in tolerating a full 7-day treatment course. This problem is circumvented by combining a 3-day course of quinine with other agents. For severe disease, intravenous (IV) quinine is a standard therapy but is not as efficacious as IV artesunate.

Primaquine and Tafenoquine

Primaquine (typically 30 mg daily for 14 days)[A9] and tafenoquine (a single 300-mg dose)[A10,A11] are related aminoquinolines that are the only available drugs to eradicate dormant liver forms of *P. vivax* and *P. ovale* and to prevent the relapses that will otherwise occur often after therapy with chloroquine and other agents. Primaquine and tafenoquine are also alternative agents for chemoprophylaxis against *P. falciparum* and other species. Both drugs can cause hemolysis or methemoglobinemia (Chapter 144) in individuals who have a deficiency in glucose-6-phosphate dehydrogenase (G6PD) (Chapter 147), and patients should be tested for this deficiency before prescribing these drugs. A single low dose of primaquine in conjunction with artemisinin-based combination therapy can lower transmission to mosquitoes.

Inhibitors of Folate Metabolism

Inhibitors of dihydrofolate reductase and dihydropteroate synthase are used in fixed-dose combination regimens for the treatment and prevention of malaria, although resistance of *P. falciparum* to sulfadoxine–pyrimethamine is common in most endemic areas. For chemoprophylaxis, sulfadoxine–pyrimethamine is no longer recommended because of drug resistance and rare life-threatening dermatologic toxicities. However, less frequent dosing in intermittent preventive therapy regimens has been well tolerated and has decreased malaria in high-risk African groups, particularly pregnant women and young children, although efficacy is limited by drug resistance. Seasonal malaria chemoprevention with monthly combined sulfadoxine–pyrimethamine and amodiaquine during the transmission season is now recommended for malaria control in areas of Africa with highly seasonal transmission and limited drug resistance, mostly in West Africa.

Atovaquone–Proguanil (Malarone)

This fixed-dose combination of a dihydrofolate reductase inhibitor pro-drug and atovaquone, which has a unique antimalarial mechanism, has excellent efficacy against most *P. falciparum* infections. It is approved for both treatment and chemoprophylaxis of *P. falciparum* malaria and other species in the United States, where it is now widely used for both indications. Malarone offers excellent efficacy with minimal toxicity. Adverse effects may include gastrointestinal symptoms, elevations in liver enzymes, headache, and rash. Widespread use in developing countries is limited by high cost and concerns about resistance.

Antibiotics

A number of antibacterials are slow-acting antimalarials. Tetracyclines and clindamycin should not be used alone to treat malaria but are combined with quinine to allow a shorter duration of therapy with that drug. In addition, doxycycline is effective in chemoprophylaxis of most *P. falciparum* malaria and is recommended for this purpose by the CDC, in particular for travelers to regions of Southeast Asia, where malarial parasites have high-level resistance to other drugs.

Multimodal Treatment of Severe Malaria

Severe malaria is a medical emergency and requires parenteral therapy. With appropriate prompt therapy and supportive care, rapid recoveries may be seen even in very ill individuals. Standard therapy for severe malaria is IV artesunate (see Table 316-1). If acquisition is delayed, short-term therapy with an oral agent is appropriate until IV artesunate is available. Appropriate care of severe malaria includes close nursing care; maintenance of fluids, electrolytes, and glucose; respiratory and hemodynamic support; and consideration of anticonvulsants for seizures (Chapter 372). Blood glucose levels should be observed closely, with glucose replacement as needed. Transfusions should be avoided when possible but play a key role in the management of patients with severe anemia. For respiratory failure, mechanical ventilation can be life-saving. Presumptive use of antibiotics is warranted when signs of sepsis are noted. Hemofiltration or hemodialysis can be life-saving for acute renal failure (Chapter 117). Aggressive fluid resuscitation, blood transfusion for moderate anemia, exchange transfusion, and specific treatment of acidosis are of uncertain value. The course of IV artesunate should be followed by oral longer-acting drugs, typically a full course of an oral artemisinin-based combination therapy, Malarone, mefloquine, or quinine plus doxycycline or clindamycin.

PREVENTION

Key malaria control interventions in malaria-endemic regions are personal protection against mosquito bites with insecticide-impregnated bed nets[A12]; control of mosquito vectors with residual spraying of insecticides; routine prompt use of artemisinin-based combination therapies, which offer rapid control of malaria infections and activity against gametocytes to limit transmission to mosquitoes; and selected use of intermittent preventive therapies to decrease malarial incidence in high-risk groups. A long-lasting piperonyl butoxide-treated insecticidal net and indoor residual spraying interventions have shown improved control of a malaria transmission compared with standard long-lasting insecticidal nets.[A13–A15] However, elimination remains challenging in many areas, in part because asymptomatic individuals infected with malaria parasites can be major drivers of transmission.[I4] Reactive focal vector control and reactive focal mass drug administration, whether implemented alone or in combination, can reduce malaria transmission compared with standard screening and treatment of individuals in close proximity to index cases.[A16] Ivermectin,[I5] which is used to treat some helminth infections, is also mosquitocidal and can reduce malaria transmission when provided in addition to standard malaria therapy.[A17] Daily prophylactic trimethoprim–sulfamethoxazole (typically 1 double-strength tablet daily), which is commonly used to prevent opportunistic infections in individuals with HIV infection, has some protection against malaria in Africa.

The RTS,S vaccine, which is based on an immunogenic sporozoite antigen, is now recommended for the prevention of falciparum malaria in children who live in regions with moderate to high transmission. This recommendation is based on multiple clinical trials that showed about 25 to 50% protection in the year after immunization (but lower levels of protection in very young children in areas of highest malaria exposure), though less protection over longer periods of time.[A18] R21, another vaccine based on the same antigen, recently demonstrated about 75% preventive efficacy.[A19] Based on these results, a new concept is seasonal malaria immunization, with provision of short-acting vaccines, potentially in conjunction with preventive drugs during the high transmission season.[A20] Another approach under study is immunization with *P. falciparum* sporozoites, with strategies including inoculation of sporozoites that are radiation-attenuated, chemoattenuated (with concurrent therapy to eliminate blood stream parasites), or genetically attenuated.[I6] Other approaches under study include preventive monoclonal antibodies[A21] and vaccines containing erythrocytic, liver-stage, and sexual-stage antigens.

Preventive Measures for Travelers to Malaria-Endemic Regions

It is important for nonimmune travelers (Chapter 265) to endemic areas to be protected against potentially lethal malaria. Travelers should decrease exposure to night-biting anopheline mosquitoes by use of insecticide repellents and sleeping in rooms that are screened or equipped with insecticide-impregnated bed nets. Standard advice for travelers to endemic areas is also to use low doses of preventive drugs chosen on the basis of the resistance profile of the particular region. Chloroquine is still recommended for malaria-endemic regions of Central America and the Caribbean. For nearly all other areas, the CDC recommends use of daily Malarone, weekly mefloquine, or daily doxycycline; details of dosing vary, but it is important to continue therapy after return from travel to eliminate parasites as they emerge from the liver (Table 316-3). Primaquine and tafenoquine (given as 200 mg/day for 3 days before departure, then 200 mg/week during travel and for 1 week post travel)[A22] offer alternative chemoprevention regimens. For areas with high risk of *P. vivax* malaria, some authorities recommend a full treatment course of primaquine after travel to

TABLE 316-3 ORAL CHEMOPROPHYLAXIS OF MALARIA*

AREAS WITH CHLOROQUINE-RESISTANT *PLASMODIUM FALCIPARUM*	
Malarone	1 tablet (250 mg artesunate/100 mg proguanil) daily
Mefloquine	250 mg weekly
Doxycycline	100 mg daily
Primaquine†	30 mg daily during exposure (chemoprophylaxis) or 30 mg daily for 14 days (terminal prophylaxis against *P. vivax* and *P. ovale*)
Tafenoquine†	200 mg daily for 3 days prior to travel, then 200 mg weekly during travel
AREAS WITHOUT CHLOROQUINE-RESISTANT *P. FALCIPARUM*	
Chloroquine phosphate	500 mg weekly

*Recommendations may change on the basis of drug resistance patterns. For additional details and pediatric dosing, see Centers for Disease Control and Prevention guidelines (http://www.cdc.gov). Begin 1 to 2 weeks before travel for mefloquine and 2 days before for doxycycline, Malarone, and primaquine; continue for 4 weeks after leaving the endemic area (1 week for Malarone and tafenoquine; 2 weeks for primaquine). All doses refer to salts unless indicated.

†Use primaquine only after demonstrating normal levels of glucose-6-phosphate dehydrogenase.

eliminate dormant liver stages. No chemoprophylaxis or mosquito avoidance methods are fully protective, so consideration of malaria as a cause of fever in returned travelers is essential (Chapter 265).

PROGNOSIS

Patients with malaria caused by *P. vivax, P. ovale,* or *P. malariae* generally respond well to chloroquine and make an uneventful recovery. Chloroquine-resistance is increasing with *P. vivax* from many areas; failures of initial treatment are usually not dangerous but should be followed by treatment with another regimen, such as an artemisinin-based combination therapy, Malarone, or mefloquine.

Patients with *P. falciparum* malaria also generally respond well to prompt therapy as long as the disease is not overly advanced at presentation. The mortality rate in patients with uncomplicated *P. falciparum* malaria is about 0.1%. For cerebral malaria, the mortality rate is 15 to 25%, with about 10% developing persistent neurologic sequelae, but many patients do remarkably well with appropriate therapy.

A common cause of death from *P. falciparum* malaria, in particular in children in endemic areas, is severe anemia. With frequent malarial infections and chronic anemia, children are ill equipped to manage acute worsening of the anemia caused by acute malarial illness. With limited access to health care, children often present for medical care late in the course of illness if at all and many deaths result. Key contributing factors to most deaths from *P. falciparum* malaria are delays between the appearance of symptoms and presentation for definitive therapy, as well as the use of suboptimal therapies. Presentation with high-level parasitemia (>200,000 parasites/μL or >5% parasitemia) or signs of severe malaria are predictive of a poor outcome. However, with aggressive support, even individuals with severe disease can often experience complete recoveries.

317 AFRICAN SLEEPING SICKNESS

WILLIAM A. PETRI, JR.

DEFINITION

Human African trypanosomiasis, commonly known as sleeping sickness, is a vector-borne parasitic disease transmitted to humans and animals by the bite of the tsetse fly (genus *Glossina*). Infection is caused by protozoa of the genus *Trypanosoma* and species *brucei*. In humans, two forms of illness are caused by two distinct subspecies that are morphologically identical but differ in their geographic range and clinical presentations. *Trypanosoma brucei gambiense* is typically found in West and Central Africa and *Trypanosoma brucei rhodesiense* in East Africa. *T. b. gambiense* has a more chronic course, whereas *T. b. rhodesiense* causes a rapid disease course; both have late stages marked by meningoencephalitis that results in coma and death if untreated. A third subspecies, *Trypanosoma brucei*, causes chronic infection called nagana in cattle, but humans are not susceptible to this organism. Chagas disease, or American trypanosomiasis, is covered in Chapter 318.

The Pathogen

The surface of the trypanosome is covered by a dense, homogeneous coat of variant surface glycoproteins (VSGs), which are immunodominant. Each individual trypanosome expresses only one VSG at a time but possesses more than 1000 different silent copies of the VSG gene, and switching to a new VSG occurs at a frequency of about 1 per million parasites. Hence, the trypanosomes expressing a given VSG will eventually be cleared by the host's antibody response, but any individual trypanosome that has switched to a new VSG will evade immune clearance, thereby resulting in a new peak of parasitemia.[1]

TABLE 316-3 ORAL CHEMOPROPHYLAXIS OF MALARIA*

AREAS WITH CHLOROQUINE-RESISTANT *PLASMODIUM FALCIPARUM*	
Malarone	1 tablet (250 mg artesunate/100 mg proguanil) daily
Mefloquine	250 mg weekly
Doxycycline	100 mg daily
Primaquine†	30 mg daily during exposure (chemoprophylaxis) or 30 mg daily for 14 days (terminal prophylaxis against *P. vivax* and *P. ovale*)
Tafenoquine†	200 mg daily for 3 days prior to travel, then 200 mg weekly during travel
AREAS WITHOUT CHLOROQUINE-RESISTANT *P. FALCIPARUM*	
Chloroquine phosphate	500 mg weekly

*Recommendations may change on the basis of drug resistance patterns. For additional details and pediatric dosing, see Centers for Disease Control and Prevention guidelines (http://www.cdc.gov). Begin 1 to 2 weeks before travel for mefloquine and 2 days before for doxycycline, Malarone, and primaquine; continue for 4 weeks after leaving the endemic area (1 week for Malarone and tafenoquine; 2 weeks for primaquine). All doses refer to salts unless indicated.

†Use primaquine only after demonstrating normal levels of glucose-6-phosphate dehydrogenase.

eliminate dormant liver stages. No chemoprophylaxis or mosquito avoidance methods are fully protective, so consideration of malaria as a cause of fever in returned travelers is essential (Chapter 265).

PROGNOSIS

Patients with malaria caused by *P. vivax, P. ovale,* or *P. malariae* generally respond well to chloroquine and make an uneventful recovery. Chloroquine-resistance is increasing with *P. vivax* from many areas; failures of initial treatment are usually not dangerous but should be followed by treatment with another regimen, such as an artemisinin-based combination therapy, Malarone, or mefloquine.

Patients with *P. falciparum* malaria also generally respond well to prompt therapy as long as the disease is not overly advanced at presentation. The mortality rate in patients with uncomplicated *P. falciparum* malaria is about 0.1%. For cerebral malaria, the mortality rate is 15 to 25%, with about 10% developing persistent neurologic sequelae, but many patients do remarkably well with appropriate therapy.

A common cause of death from *P. falciparum* malaria, in particular in children in endemic areas, is severe anemia. With frequent malarial infections and chronic anemia, children are ill equipped to manage acute worsening of the anemia caused by acute malarial illness. With limited access to health care, children often present for medical care late in the course of illness if at all and many deaths result. Key contributing factors to most deaths from *P. falciparum* malaria are delays between the appearance of symptoms and presentation for definitive therapy, as well as the use of suboptimal therapies. Presentation with high-level parasitemia (>200,000 parasites/μL or >5% parasitemia) or signs of severe malaria are predictive of a poor outcome. However, with aggressive support, even individuals with severe disease can often experience complete recoveries.

317 AFRICAN SLEEPING SICKNESS

WILLIAM A. PETRI, JR.

DEFINITION

Human African trypanosomiasis, commonly known as sleeping sickness, is a vector-borne parasitic disease transmitted to humans and animals by the bite of the tsetse fly (genus *Glossina*). Infection is caused by protozoa of the genus *Trypanosoma* and species *brucei*. In humans, two forms of illness are caused by two distinct subspecies that are morphologically identical but differ in their geographic range and clinical presentations. *Trypanosoma brucei gambiense* is typically found in West and Central Africa and *Trypanosoma brucei rhodesiense* in East Africa. *T. b. gambiense* has a more chronic course, whereas *T. b. rhodesiense* causes a rapid disease course; both have late stages marked by meningoencephalitis that results in coma and death if untreated. A third subspecies, *Trypanosoma brucei*, causes chronic infection called nagana in cattle, but humans are not susceptible to this organism. Chagas disease, or American trypanosomiasis, is covered in Chapter 318.

The Pathogen

The surface of the trypanosome is covered by a dense, homogeneous coat of variant surface glycoproteins (VSGs), which are immunodominant. Each individual trypanosome expresses only one VSG at a time but possesses more than 1000 different silent copies of the VSG gene, and switching to a new VSG occurs at a frequency of about 1 per million parasites. Hence, the trypanosomes expressing a given VSG will eventually be cleared by the host's antibody response, but any individual trypanosome that has switched to a new VSG will evade immune clearance, thereby resulting in a new peak of parasitemia.[1]

ABSTRACT

Human African trypanosomiasis, commonly known as sleeping sickness, is a vector-borne parasitic disease transmitted to humans and animals by the bite of the tsetse fly. Infection is caused by protozoa of the genus *Trypanosoma* and species *brucei*. In humans, two forms of illness are caused by two distinct subspecies that are morphologically identical but differ in their geographic range and clinical presentations. *Trypanosoma brucei gambiense* is typically found in West and Central Africa and *Trypanosoma brucei rhodesiense* in East Africa. *T. b. gambiense* has a more chronic course, whereas *T. b. rhodesiense* causes a rapid disease course; both have late stages marked by meningoencephalitis that results in coma and death if untreated. Treatment depends on the infecting organism and the stage of disease.

KEYWORDS

African sleeping sickness
Trypanosoma brucei
tsetse fly
pentamidine
nifurtimox
eflornithine
meningoencephalitis

Recombination between VSG alleles ensures a virtually limitless repertoire of new VSGs, so antibody-mediated parasite eradication is impossible.

EPIDEMIOLOGY

Human African trypanosomiasis is diminishing in importance as a result of increased in public health control efforts. In the past, major epidemics occurred in the Congo basin and Uganda between 1896 and 1906, in numerous endemic countries in the 1920s, and then again in the early 20th century. More recently, however, access of at-risk populations to diagnosis and treatment has led to a dramatic reduction to less than 2000 cases in 2017-2018. Since 2015, more than 90% of reported cases are due to *T. b. gambiense*, the majority being from the Democratic Republic of the Congo, and less than 100 cases of *T. b. rhodesiense* have been reported annually since 2015. However, many people are thought to die of human African trypanosomiasis without an accurate diagnosis, and African trypanosomiasis remains a looming threat to an estimated 60 million people who live in tsetse fly–inhabited areas among 36 countries of sub-Saharan Africa.[2]

The geographic distribution includes areas where the vector, parasite, reservoir hosts, and human hosts cohabit (E-Fig. 317-1). In general, these locales include focal areas on the African continent within 15 degrees north and 15 degrees south latitude, with a predilection for wooded rural areas. Humans at greatest risk for infection rely on animal husbandry, agriculture, fishing, and hunting for their livelihoods. Often, disease is concentrated among foci of rural areas, having significant socioeconomic impact on affected villages. With a few exceptions, this infection is never found in urban areas. Fewer than 50 cases are reported annually outside of Africa, usually the result of travel by North Americans or Europeans to African game reserves.[3]

T. b. gambiense is transmitted by tsetse flies from the *Glossina palpalis* group. Tsetse flies are typically found along riverbanks of wooded areas in the more tropical areas of Central and West Africa. *T. b. gambiense* is not generally considered a zoonotic disease. The reservoir hosts and the focus of public health campaigns are mainly humans. The role of animal reservoirs for this organism remains undetermined, but natural infections have been reported in domestic animals such as dogs, sheep, cattle, and pigs.

T. b. rhodesiense is transmitted by tsetse flies that belong to the *Glossina morsitans* group and that are commonly found among woodland and savannah areas of East and Central Africa. *T. b. rhodesiense* is a zoonotic disease with numerous wild and domestic species of animals acting as reservoirs that sustain the parasite. Domestic species, especially cattle, can drive outbreaks and, as a result, are the focus of successful prevention campaigns.

PATHOBIOLOGY

After the bite of a tsetse fly carrying metacyclic trypomastigotes, a local reaction (chancre) may form at the inoculation site. This sign is seen with *T. b. rhodesiense* infection and is more frequently observed in travelers, but it is rarely seen with *T. b. gambiense* infection. Parasites subsequently disseminate into the blood and lymphatic systems in what is considered stage I of the disease. Spread of the parasites into the central nervous system (CNS) defines stage II of the disease, which is invariably fatal if untreated. The parasite appears to remain extracellular throughout the course of infection. As an extracellular microbe, the parasite must evade immune clearance to establish a persistent infection.

Peaks and waves of parasitemia occur during stage I disease and result in the classic symptom of intermittent fever. These bouts of fever correspond to a type 1 inflammatory response (Chapter 36), in which classically activated macrophages produce high levels of tumor necrosis factor (TNF) and nitric oxide. This response helps control the parasitemia but also contributes to tissue damage. Type 2 inflammatory responses with high levels of interleukin-10 then limit the production of TNF and nitric oxide after the initial parasitemia has been controlled. Antibody responses are directed to VSGs and other trypanosome antigens (e.g., antigens from lysed parasites), but autoantibodies are also produced. Generalized febrile episodes are observed in association with lymphadenopathy, myocardial inflammation, and pericardial inflammation. Cardiac involvement is typically more severe with *T. b. rhodesiense* infection.

In stage II of the disease, parasites cross the blood-brain barrier and invade the CNS. Acute meningoencephalitis develops, and the variety of inflammatory cells that infiltrate the brain include macrophages, lymphocytes, plasma cells, Mott cells (plasma cells with spherical cytoplasmic inclusions composed of immunoglobulin), and morular cells (plasmacytoid cells with transparent hyaline vesicles in the cytoplasm). These inflammatory cells are found in the meninges, which become thickened, as well as in the perivascular spaces and neuropil. Edema, hemorrhage, and granulomatous lesions are often present; thrombosis and neuronal degeneration may also be observed.

Genetic resistance to African sleeping sickness is due to a common (in individuals of African descent) polymorphism in the gene for $APOL_1$, which is a component of high-density lipoprotein. This gene product mediates serum resistance to the parasite. An untoward consequence of this polymorphism is that individuals with two copies of the variant allele (15% of African Americans) are at increased risk of chronic kidney disease (Chapter 107).[4]

CLINICAL MANIFESTATIONS

The clinical manifestations of human African trypanosomiasis differ on the basis of the infecting organism. *T. b. gambiense* usually is more of a chronic disease, with an estimated average duration of 3 years. By comparison, infection with *T. b. rhodesiense* progresses much more rapidly, leading to coma and death within weeks to months. However, infection with *T. b. gambiense* also can cause a rapid decline. Other similarities include an early hemolymphatic stage (stage I) and a late stage characterized by prominent CNS disease, including meningoencephalitis (stage II).[5]

West African Sleeping Sickness

Infection starts after the bite of a fly infected with *T. b. gambiense*. At the site of inoculation, a painful, indurated, and erythematous trypanosomal chancre may develop 1 to 2 weeks after the bite and resolve spontaneously after several weeks. On occasion, the chancre may ulcerate. However, these features are rarely seen at the time of clinical presentation and sometimes are not known to have occurred on history; thus many patients develop disseminated disease without awareness of a localized infection.

The hemolymphatic stage, when parasites disseminate throughout the body, may not be manifested clinically until weeks or months after the initial bite. Typical symptoms include intermittent spiking fevers, occasionally accompanied by headaches and malaise. These features may persist for weeks or months because of the cyclic nature of parasitemia and antibody production against the various antigens sequentially expressed by the parasite.

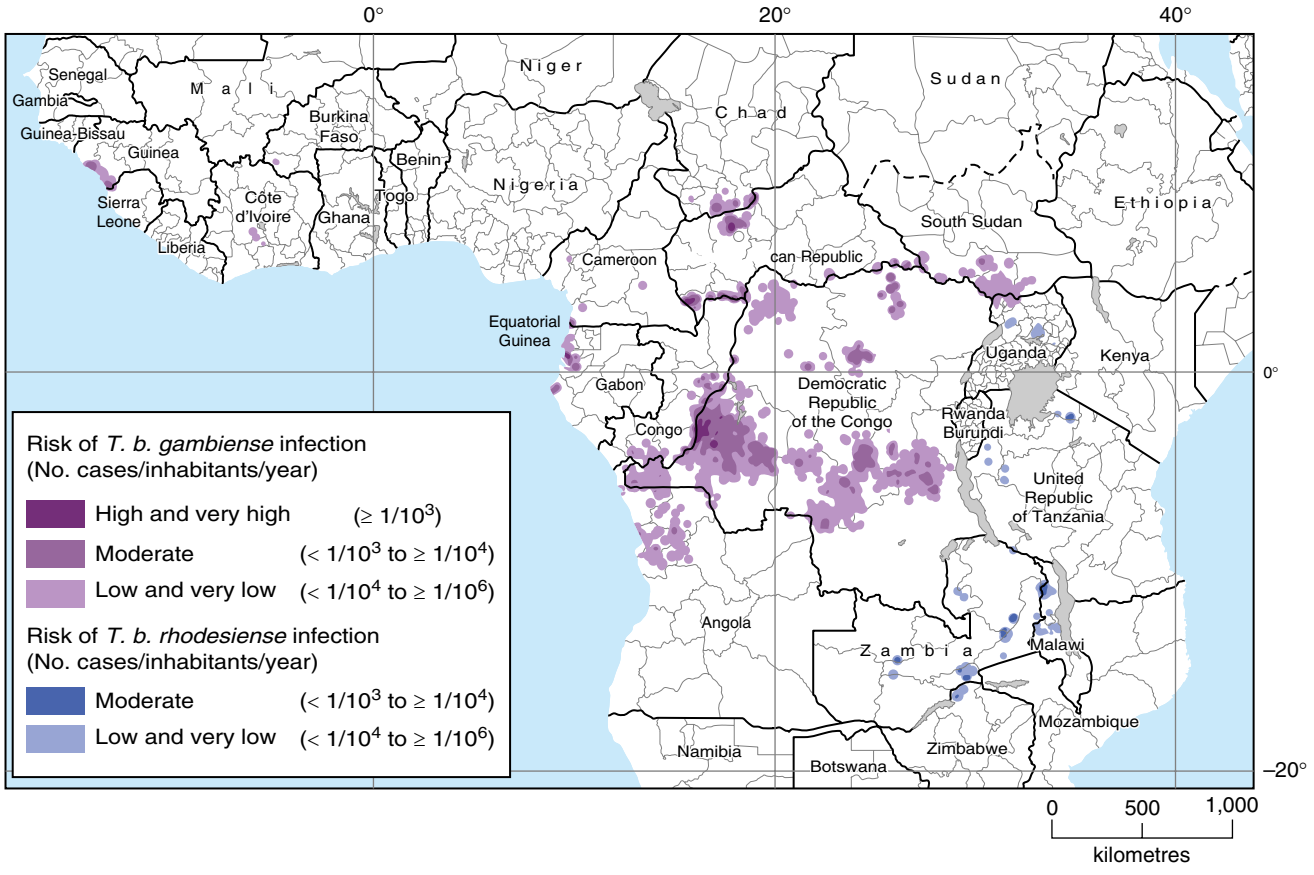
Lymphadenopathy (Chapter 154) is a common finding in West African sleeping sickness. Whereas regional lymphadenopathy may develop after the initial bite, generalized lymphadenopathy around the head and neck is often found as chronic illness develops. Enlargement of nodes in the posterior cervical triangle, commonly known as Winterbottom sign, is the classic finding, but other cervical and supraclavicular nodes may also be involved. Affected nodes are discrete, movable, rubbery nodes that are nontender to palpation; over time, they may become more indurated because of fibrosis.

Other symptoms reported include pruritus, occasionally accompanied by rash, arthralgias, and periarticular swelling, as well as by transient edema of the extremities and face. Less common symptoms include features consistent with neuroendocrine dysfunction, including loss of libido and impotence, amenorrhea and infertility, alopecia, and gynecomastia. Signs of disease include hepatomegaly and splenomegaly; cardiac dysfunction, including tachycardia; electrocardiographic abnormalities such as prolonged QTc intervals and repolarization changes; and, less commonly, pericarditis or myocarditis. Hemolytic anemia and derangements in liver function test results may occur.

Months or even years after the initial infection, stage II disease develops and is characterized by headaches, daytime somnolence, and neuropsychiatric features. Behavioral changes, including irritability, confusion, inability to concentrate, and lassitude, are among the first signs of CNS disease; psychosis has also been described. Neurologic findings are numerous and include a variety of motor and sensory disturbances, including extrapyramidal features, dysesthesias, and visual impairment. The symptoms have given the infections its common name of sleeping sickness and are manifested by daytime somnolence and nocturnal irritability. Late-stage disease is marked by cerebral edema and meningoencephalitis. Progressively, a loss of neurologic function can lead to paralysis. Patients may succumb to aspiration pneumonias or malnutrition; otherwise, coma leads to death in the absence of treatment.

East African Sleeping Sickness

Compared with Gambian sleeping sickness, East African sleeping sickness is more rapidly progressive. The infective bite is more frequently associated with the development of a chancre, although some studies report a chancre in only 20% of patients. An incubation period of days to weeks elapses before other signs or symptoms occur. Initial symptoms include severe intermittent fevers that may resemble those found with malaria. Posterior cervical lymphadenopathy is not as common as with *T. b. gambiense*. Skin changes are more prominent, and rashes in the early stage of infection are particularly common in expatriates with the infection. In addition, cardiac manifestations are more commonly and clinically relevant; tachycardia, arrhythmias, myocarditis, and heart failure



E-FIGURE 317-1. **Map of human African trypanosomiasis.**

may be severe enough to cause death before the development of severe CNS disease. CNS disease mirrors that of West African sleeping sickness, but the onset occurs earlier and the rate of deterioration is more rapid. Hematologic abnormalities include anemia,[6] thrombocytopenia, and disseminated intravascular coagulation. Death may ensue after weeks or months without treatment.

DIAGNOSIS

Epidemiologic clues and clinical findings may together suggest the diagnosis of human African trypanosomiasis, but definitive diagnosis relies on demonstration of the parasite. In the early stage of disease, light microscopy and Giemsa stain can visualize the highly motile parasites directly from fresh specimens of fluid expressed from chancres or lymph node aspirates. Peripheral blood smears (Figure 317-1), including Giemsa-stained thick and thin smears and bone marrow aspirates, also can show the parasite, especially blood during stage I disease when parasitemia is high. The threshold for visualization of parasites by thick smear is approximately 5000 parasites/mL, so direct visualization is more common with *T. b. rhodesiense* infection, given the higher parasite load. Polymerase chain reaction (PCR) analysis of blood, if available, is more sensitive than smears or culture of blood and lymph nodes.[7]

Serologic tests are also available to diagnose *T. b. gambiense* infection. The *T. b. gambiense* card agglutination test, which is commonly used in screening programs, has a sensitivity that ranges from 87% to 98%, depending on the population under study, with a specificity that may be as high as 95%. Rapid serologic tests for infection with *T. b. gambiense* include human African trypanosomiasis SeroStrop (which uses a dipstick method) and the human African trypanosomiasis Sero + K SeT test (which uses a lateral flow device) for testing blood or plasma, respectively. No serologic tests are available for *T. b. rhodesiense* infection.

Cerebrospinal fluid (CSF) must also be analyzed to determine the most appropriate treatment. Abnormalities in CSF include an elevated opening pressure, increased cell counts and total protein levels, and an increased polyclonal immunoglobulin M (IgM). Stage II disease is defined by the presence of more than 5 white blood cells/μL, the presence of trypanosomes, or an elevated total protein (>370 mg/L) in the CSF. PCR or latex-agglutination testing for CSF IgM hold promise but have not proven superior to direct visualization or culture.

FIGURE 317-1. ***Trypanosoma rhodesiense*** **in peripheral blood. It has a nucleus, posterior kinetoplast, undulating membrane, and flagellum (×1500).**

TREATMENT

Very few drugs have been available for treatment of human African trypanosomiasis, and those that have been commonly used are quite toxic (Table 317-1). Treatment depends on the infecting organism and the stage of disease. Distribution of drugs is through the World Health Organization (WHO) in Geneva.

For stage I *T. b. gambiense* infection, pentamidine is the drug of choice.[A1] The standard regimen is daily parenteral administration for 1 week.

For stage I *T. b. rhodesiense*, suramin[8] is administered in a slow intravenous infusion periodically during 3 weeks. Although anaphylaxis is rare (approximately 1 in 20,000 patients), a test dose is recommended before full treatment is initiated. A number of side effects, including nephrotoxicity, require close monitoring. Urinalysis is recommended before each dose, and the drug should be discontinued if proteinuria persists and casts are seen in the urine sediment.

For stage II *T. b. gambiense*, the treatment of choice is a combination of nifurtimox and eflornithine.[A2] Nifurtimox is administered orally, whereas eflornithine requires frequent intravenous administration. For stage II *T. b. rhodesiense* infection, melarsoprol remains the only available agent; it is a highly effective but impressively toxic drug that can be used for stage II disease with either organism. The side effects are numerous, but the most important is the life-threatening encephalopathy that may develop from the arsenic (highly fatal) or as an inflammatory reaction. Concomitant corticosteroid administration under expert guidance is helpful in reducing the risk of encephalopathy and death without compromising the efficacy of melarsoprol. The risks of encephalopathy can be reduced by a gradual increase in the first round of treatment between 2 and 3.6 mg/kg in divided doses three times daily during 3 days. Unfortunately, resistance to melarsoprol is widespread.[9]

Few therapeutic options are available to treat the late stage of African trypanosomiasis. However, oral fexinidazole,[10] given once daily orally, is effective and safe for *T. b. gambiense* infection.[A3] It is also an option for stage I and stage II disease.[11]

PREVENTION

No vaccine is available against human African trypanosomiasis. The mainstays of prevention include active case finding with early treatment and vector control.[12] Given the nature of each infection, active case surveillance is more suitable for infection with *T. b. gambiense*, but vector control is more effective for prevention of infection with *T. b. rhodesiense*. The goal of active case finding is to identify infected individuals who may still be in the asymptomatic stage or early stage. This approach, which is more suited for disease from *T. b. gambiense*, typically consists of a screening examination for lymphadenopathy

TABLE 317-1 DRUGS USED TO TREAT HUMAN AFRICAN TRYPANOSOMIASIS

DRUG	CLASS	STAGE	ROUTE	ADULT DOSE	ADVERSE EFFECTS
TRYPANOSOMA BRUCEI GAMBIENSE					
Pentamidine	Aromatic diamidine	I	IM or IV	4 mg/kg daily for 7 days	Pain, GI symptoms, hypoglycemia or hyperglycemia, electrolyte abnormalities, leukopenia, thrombocytopenia
Eflornithine	Ornithine carboxylase inhibitor	II	IV	100 mg/kg q6h for 14 days	GI symptoms, bone marrow toxicity, seizures
Eflornithine plus nifurtimox				Nifurtimox 15 mg/kg per day orally in three doses × 10 days; eflornithine 400 mg/kg per day intravenously in two 2-h infusions (each dose diluted in 250 mL of water for injection) × 7 days	
TRYPANOSOMA BRUCEI RHODESIENSE					
Suramin	Polysulfonated naphthylamine derivative of urea	I	IV	1 g IV on days 1, 3, 7, 14, and 21 (after test dose of 100-200 mg)	Anaphylaxis, nephrotoxicity, fever, rash, pruritus, arthralgias, reversible peripheral neuropathy, and bone marrow toxicity
Melarsoprol	Trivalent arsenical	II	IV	1.2 mg/kg q8h for 3 consecutive days each week for 3 weeks (maximum daily dose, 180 mg)	Encephalopathic syndromes, peripheral neuropathy, paralysis, cardiac dysrhythmias, GI symptoms, rash, pruritus, thrombophlebitis. Resistance to melarsopol also a problem.

GI = gastrointestinal; IM = intramuscular; IV = intravenous.

followed by serologic testing. If results are positive for both, the patient should undergo further evaluation with lymph node aspirate and blood testing. If PCR is positive or trypanosomes are seen, the patient should be treated.

Vector control measures include tsetse fly traps and insecticide-impregnated screens; the traps are easily maintained by locals, but the screens require regular retreatment, so they are more labor intensive and costly to maintain. Mass spraying is not routinely used, but ground or aerial spraying combined with disruption of the animal reservoir's habitat may be the most effective method of achieving rapid vector control during an epidemic.

Travelers to endemic areas should be aware of this disease and should use basic protective measures. Protective clothing of at least medium weight should be worn; neutral colors are most effective because flies are attracted to bright and dark colors. Tsetse flies are attracted to moving vehicles but rest in the shade or bushes. Although use of insect repellant is prudent for other vector-borne illnesses that may be endemic in these areas, it has not been proven to reduce the risk of tsetse fly bites. There is no recommended chemoprophylaxis for travelers.

PROGNOSIS

Stage I disease is treatable and curable. Stage II disease is uniformly fatal if untreated, but about 95% of treated patients can be cured of late-stage disease, usually with a resolution of symptoms.

318 CHAGAS DISEASE

LOUIS V. KIRCHHOFF

DEFINITION

Chagas disease, or American trypanosomiasis, is caused by the protozoan parasite *Trypanosoma cruzi*. The terms *Chagas disease*, *American trypanosomiasis*, and *T. cruzi infection* are synonyms.

The Pathogen

Several dozen species are included in the genus *Trypanosoma*, but only the African trypanosome *Trypanosoma brucei* (subspecies *T. b. gambiense* [West African] and *T. b. rhodesiense* [East African]) (Chapter 317) and the American trypanosome *T. cruzi* cause disease in humans.

EPIDEMIOLOGY

Epizootiology of *T. cruzi*

Many species of triatomine insects, also called kissing bugs, act as vectors for *T. cruzi*, and many species of wild and domestic mammals, as well as humans, are involved in the complex lifecycle of this organism. The triatomine vectors that transmit *T. cruzi* are found in the Americas from southern Argentina through the southern half of the United States. The parasite has been isolated from more than 100 species of domestic and wild mammals, which for the most part become infected when they eat infected vectors or through congenital transmission. Armadillos, wood rats, raccoons, and opossums are typical wild mammalian reservoirs, and these and other species that harbor *T. cruzi* can be found in large numbers in the southern and southwestern parts of the United States.

Typically, humans acquire *T. cruzi* infection, which is lifelong, when they live in houses in enzootic areas where the sylvatic cycle of transmission is active. The process begins when vector species adaptable to living in human dwellings take up residence in niches in the primitive wood, mud, and stone houses that are typical in many endemic regions. These vectors become domiciliary, and they then take blood meals, mostly at night, from the humans who occupy the dwellings that they have invaded, as well as from domestic animals that sleep there, particularly dogs.[1] Thus, Chagas disease is primarily a public health problem among poor people who live in rural areas.

Endemic Chagas Disease

Chagas disease is a zoonosis that is endemic in Mexico and in all the countries of Central and South America, but it is not endemic in the Caribbean islands. In 2018, the Pan American Health Organization estimated that in the 21 endemic countries, 6 to 8 million people are chronically infected with *T. cruzi*, 28,000 new cases occur each year, and up to 12,000 deaths result from Chagas disease annually.[2] Since 1991, a major international vector control program in the southern countries of South America (Chile, Argentina, Paraguay, Brazil, Bolivia, and Uruguay) has achieved a marked reduction in vector transmission of *T. cruzi* through housing improvement, education of people at risk for acquiring the infection, and spraying insecticides.[3] Substantial reductions in prevalence rates in school-aged children and in blood donors constitute clear evidence of the success of the program. Uruguay, Chile, and Brazil were certified as being free of vector transmission in 1997, 1999, and 2006, respectively. Marked reduction in transmission has been achieved in Argentina as well. Similar programs have been initiated in Central America and the Andean countries. In parallel with the vector control programs, donor screening has been implemented throughout almost the entire endemic range.

Chagas Disease in the United States

The sylvatic cycle of *T. cruzi* exists in much of the southern and southwestern regions of the United States, but only seven cases of autochthonous (disease spread from one individual and acquired in another individual in the same place) acute Chagas disease have been reported: four in Texas and one each in Tennessee, Louisiana, and California. Moreover, in the first 4 years of U.S. blood donor screening starting in January of 2007, only 16 *T. cruzi*–infected donors, all of whom appeared to have acquired the infection autochthonously, were identified in approximately 29 million units. Only two cases of acute *T. cruzi* infection have been reported in tourists returning to the United States, but three such instances have been reported in Europe as well as one in Canada. Thus, acute Chagas disease is extremely rare in the United States, and there is no indication that its incidence is increasing.

A recent estimate puts the number of *T. cruzi*–infected persons currently living in the United States at about 240,000 to 350,000,[4] including about 40,000 women of childbearing age.[5] Since blood donor screening began in the United States in 2007, more than 100 million units have been screened, and several thousand *T. cruzi*–infected donors have been identified and permanently deferred from donation. The confirmed rate of *T. cruzi* infection in donors is about 1 in 13,300. With the goal of reducing the enormous cost of universal screening ($100 to $200 million per year), a U.S. Food and Drug Administration (FDA)-approved selective screening protocol based on previous negative test results has been implemented.

In Europe, infection is seen primarily in Latin American immigrants to Spain, Italy, France, the United Kingdom, and Switzerland. The pooled seroprevalence among such immigrants is about 4%, with an 18% seroprevalence among immigrants from Bolivia. In the United States, transplantation of organs from three persons with undiagnosed chronic *T. cruzi* infection resulted in acute Chagas disease in five recipients, one of whom died of the infection. To date, two instances of congenital transmission of *T. cruzi* here have been reported. A reasonable estimate of the number of babies born in the United States each year with congenital Chagas disease ranges from 63 to 315. Most babies with congenital Chagas disease are asymptomatic, and limited knowledge about congenital Chagas disease leads to underreporting.

PATHOBIOLOGY

T. cruzi vectors become infected by ingesting blood from mammals that have parasites in their blood stream. The parasites then multiply in the gut of the

PATHOBIOLOGY

T. cruzi vectors become infected by ingesting blood from mammals that have parasites in their blood stream. The parasites then multiply in the gut of the

ABSTRACT

Chagas disease, or American trypanosomiasis, is a zoonotic infection caused by the single-cell protozoan parasite, *Trypanosoma cruzi*. *T. cruzi* is spread by blood-sucking triatomine insects among its various mammalian hosts, which include domestic and wild animals as well as humans. *T. cruzi* also can be transmitted from mother to fetus, through blood products and organ transplantation, by ingestion of contaminated food and drink, and in laboratory accidents. Infection with *T. cruzi* in humans is lifelong. Chagas disease is endemic in Mexico, as well as in all the countries of Central and South America but not in any of the Caribbean islands. Approximately 6 to 8 million persons are chronically infected with *T. cruzi,* about 28,000 new infections occur each year, and roughly 12,000 persons die of the illness annually. An estimated 240,000 to 350,000 immigrants with Chagas disease from endemic countries currently live in the United States. About 10 to 30% of persons who are chronically infected with *T. cruzi* ultimately develop cardiac and/or gastrointestinal symptoms related to the persistent presence of the parasite. The diagnosis of acute and congenital Chagas disease is made by parasitologic methods, typically direct microscopic examination of blood or polymerase chain reaction (PCR) assay. Chronic *T. cruzi* infection is diagnosed serologically. Nifurtimox and benznidazole are the only two drugs available for treating *T. cruzi* infections, and the latter is preferred by most experts. Parasitologic cure rates are relatively high for acute and congenital infections but unfortunately very low in persons with long-standing infections. No convincing data from randomized controlled trials indicate that treatment of chronically infected persons with either drug significantly affects long-term outcomes.

insects and are ultimately discharged in the feces of the vector. Transmission to a new mammalian host occurs when parasite-laden vector feces contact the mucosae of the mouth or nose, the conjunctivae, or breaks in the skin. The contaminating parasites enter local cells and multiply intracellularly; as parasitized cells rupture, they are released into the lymphatics and blood stream. The circulating organisms enter new cells at distant sites and maintain an endless process of asynchronous multiplication. The life cycle is completed as parasites are swept up in blood meals taken by vectors.[6] In addition to vector-borne transmission, *T. cruzi* can be transmitted by blood or organs donated by infected persons, from mother to unborn child,[7] by the ingestion of contaminated food or drink,[8,9] and in laboratory accidents.

In acute Chagas disease, an inflammatory lesion, called a chagoma, may appear at the site where the parasite enters. Local histologic changes include intracellular parasitism of muscle and other subcutaneous tissues, lymphocytic infiltration, interstitial edema, and hyperplasia of lymph nodes that drain the area. As the parasites spread systemically through the lymphatics and blood stream, the most heavily parasitized tissues are muscles, including the myocardium, but the organisms can invade essentially any tissue. Myocarditis may develop in association with focal areas of infected cardiomyocytes, inflammation, and necrosis. The characteristic pseudocysts seen in sections of *T. cruzi*–infected tissues are actually host cells filled with multiplying forms of the parasite (Fig. 318-1). In some patients, parasites can be seen in cerebrospinal fluid (CSF).

In persons with chronic Chagas disease, the heart is the organ most commonly affected. Hearts obtained at autopsy from patients who died of Chagas cardiomyopathy usually have a global appearance reflecting biventricular enlargement and thinning of ventricular walls (E-Fig. 318-1). Mural thrombi are frequently present, and an apical aneurysm of the left ventricle is typical in patients with advanced disease. At the cellular level, the process that underlies these gross pathologic abnormalities is a chronic inflammation with mononuclear cell infiltration, diffuse interstitial fibrosis, and atrophy of myocardial cells. The chronic inflammation also affects the conduction system and causes a variety of rhythm disturbances, including atrial bradyarrhythmias and fibrillation; premature ventricular contractions; left anterior fascicular block; bundle branch blocks, often of the right bundle; ventricular tachycardia; and third-degree atrioventricular block. Parasites are rarely seen in diseased tissues by conventional histologic methods, but several studies using polymerase chain reaction (PCR) assays found a correlation between the intensity of inflammation and the presence of parasites. Evidence accumulated to date implicates the persistence of parasites and the resulting chronic inflammation in affected tissues—rather than autoimmune mechanisms—as the basis for the pathogenesis in patients with chronic *T. cruzi* infection.

Chagas disease of the digestive tract can cause striking dilation and hypertrophy of the esophagus or colon. Focal inflammatory lesions with lymphocytic infiltration are seen on microscopic examination of affected tissues. The number of neurons in the myenteric plexus is reduced, and periganglion and intraganglion fibrosis with Schwann cell proliferation and lymphocytosis is present. In most patients, the clinical consequences of this parasympathetic denervation are limited to the esophagus or colon (or to both), but the ureters, biliary tree, and other hollow viscera can be affected as well.

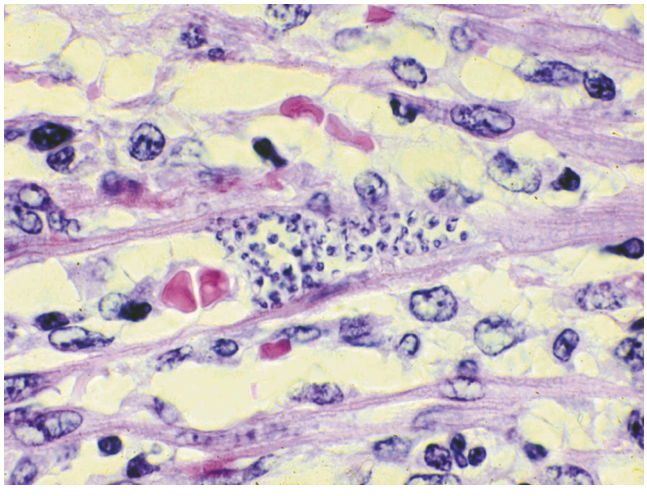

FIGURE 318-1. ***Trypanosoma cruzi*** **in cardiac muscle of a child who died of acute Chagas myocarditis. An infected myocyte containing several dozen *T. cruzi* amastigotes is in the center of the field (hematoxylin and eosin staining, ×900).**

CLINICAL MANIFESTATIONS

Acute Chagas Disease

Acute Chagas disease is usually an illness of children but can occur at any age. Symptoms are typically mild and nonspecific (Table 318-1).[10] When the parasite has entered through a break in the skin or the site of a vector's puncture, a chagoma may appear with local lymphadenopathy. The Romaña sign, which is the classic finding in acute Chagas disease, consists of painless edema of the palpebrae and periocular tissues and may appear when the conjunctiva is the portal of entry. These initial local signs can be followed by fever, malaise, anorexia, and edema of the face and lower extremities. Generalized lymphadenopathy and hepatosplenomegaly also may be present. Severe and even fatal myocarditis may develop. Meningoencephalitis is a rare complication. In untreated patients the acute illness resolves spontaneously over 6 to 8 weeks as the patient enters the indeterminate phase of Chagas disease, which is characterized by subpatent parasitemia, absence of associated signs and symptoms, and detectable specific antibodies to *T. cruzi*.

Chronic Cardiopathy

Only 10 to 30% of persons who are chronically infected with *T. cruzi* have clinical symptoms or signs, which can develop insidiously over years and often decades after the initial infection. Chagas cardiopathy often manifests as rhythm disturbances, cardiomyopathy with heart failure, and thromboembolism,[11,12] Dizziness, syncope, and even seizures can result from a wide variety of arrhythmias. The cardiomyopathy often leads to biventricular failure, and right-sided heart failure can predominate in patients with advanced disease. Chronic Chagas disease is an independent risk factor for stroke.[13]

Chronic Gastrointestinal Disease (Megadisease)

In patients with megaesophagus, symptoms are similar to those of idiopathic achalasia (Chapter 124) and may include cough, dysphagia, odynophagia, and regurgitation. Hypersalivation and consequent salivary gland hypertrophy develop in some patients with advanced esophageal dysfunction. Aspiration

TABLE 318-1 CLINICAL MANIFESTATIONS AND DIAGNOSIS OF CHAGAS DISEASE

PHASE OR FORM	CLINICAL MANIFESTATIONS	DIAGNOSIS	TREATMENT SUCCESS
Acute infection	Usually nonspecific mild symptoms	Wet prep of blood or PCR	80-100%
Congenital infection	Asymptomatic or nonspecific mild symptoms	Wet prep of blood or PCR	80-100%
Chronic infection	Asymptomatic, without ECG change	Positive serology	Benefit not established
Cardiomyopathy	Arrhythmias, syncope, left ventricular dysfunction, heart failure, ECG conduction abnormalities	Positive serology	Benefit not established
Gastrointestinal	Dilation of esophagus, colon, or both	Positive serology	Benefit not established
Reactivation in immunosuppressed hosts	Acute myocarditis, CNS abscesses, skin chagomas	Wet prep of blood or PCR	Suppression of acute symptoms and parasitemia, but long-term benefit not clear

CNS = central nervous system; ECG = electrocardiogram; PCR = polymerase chain reaction.

E-FIGURE 318-1. Chest radiograph of a patient from Bolivia with chronic *Trypanosoma cruzi* infection, rhythm disturbances, and cardiomyopathy. Pacemaker wires can be seen in the area of the left ventricle.

can occur, especially during sleep, and repeated episodes of aspiration pneumonitis are common in untreated patients. Weight loss and even cachexia can occur with severe megaesophagus.

Patients with chagasic megacolon have intermittent abdominal pain and chronic constipation, sometimes with several weeks between bowel movements. Rarely, acute obstruction, occasionally with volvulus, can lead to perforation and sepsis.

Immunosuppression and Transplantation

When persons with chronic carriage of *T. cruzi* become immunosuppressed, the infection can reactivate, sometimes with an intensity that is more severe than acute Chagas disease in immunocompetent persons. Reactivation can occur after renal transplantation, but Chagas disease is not a contraindication to kidney transplantation. When *T. cruzi*–infected patients undergo transplantation, they should have periodic monitoring for signs and symptoms of acute Chagas disease, including careful neurologic evaluation, and parasitologic testing.

Reactivation of *T. cruzi* infection can also occur in persons who are coinfected with human immunodeficiency virus (HIV) or are otherwise immunosuppressed. Although the risk is low, all such patients with geographic or maternal risk should be screened for *T. cruzi* infection.[14] HIV viral loads can increase in the context of reactivated acute Chagas disease.[15]

DIAGNOSIS

Acute Chagas Disease

The first step in considering the diagnosis of acute Chagas disease is establishing that a person is at risk for *T. cruzi* infection. Risk factors include recent residence or blood transfusion in an endemic area, birth to a mother with geographic- or transfusion-associated risk in the case of a newborn, or a laboratory accident involving the parasite.

Definitive diagnosis of acute Chagas disease requires the detection of parasites. PCR assays are the most sensitive method[16] but often are not readily available. Parasites often can be seen in wet preparations of anticoagulated blood, in a buffy coat, or in Giemsa-stained blood smears. In infected immunocompromised patients, parasites can sometimes be found in lymph node aspirates, biopsy specimens of skin lesions, bone marrow, endomyocardial tissue, CSF, and pericardial fluid.

Chronic Chagas Disease

Chronic *T. cruzi* infection is usually diagnosed by detecting immunoglobulin G (IgG) antibodies that specifically bind to parasitic antigens on at least two different serologic tests (enzyme-linked immunoassay, indirect immunofluorescence, and chemiluminescence),[17] and isolation of the organism is rarely necessary. In chronic Chagas disease, the sensitivity of PCR assays has ranged from 44.7 to 100% but has been higher than 90% in most shades. It is generally accepted that the level of sensitivity of these assays is not high enough to justify their use for confirmatory testing of serologically positive clinical or donor samples. In contrast, PCR assays may be useful in persons who have borderline serologic results, in patients suspected of having congenital or acute disease but in whom parasites are not detected microscopically, and in infected patients who have received specific treatment. In all such persons, however, the less than optimal sensitivity of PCR means that positive results can be taken as being truly indicative of infection, but a negative result does not exclude infection.

TREATMENT

Antiparasitic Drugs

The two drugs currently available for treating Chagas disease (benznidazole and nifurtimox) are of limited benefit (Chapter 315). Treatment is indicated in all patients with acute or congenital infections, as well as in chronically infected children up to age 18 years. By extension, it would be reasonable to treat anyone age 18 years or older known to have acquired *T. cruzi* infection within the past 17 years. Benznidazole is considered the drug of choice by most experts in endemic countries.

Benznidazole (at 5 mg/kg daily for 60 days) is effective in adults, and it can cure more than 90% of babies with congenital infection at 5 to 10 mg/kg/day for 60 days.[18] Side effects can include rash, peripheral neuropathy, and granulocytopenia.

In patients with acute Chagas disease, nifurtimox (8 to 10 mg/kg body weight per day for adults, 12.5 to 15 mg/kg/day for adolescents, and 15 to 20 mg/kg/day for children) in four divided doses for 90 to 120 days reduces symptoms and decreases mortality rates, with an approximately 70% rate of parasitologic cure.

Unfortunately, cure rates may be less than 10% in adults with long-standing chronic *T. cruzi* infection. Disadvantages of nifurtimox include its long course of treatment and frequent side effects, including anorexia, nausea, vomiting, weight loss, and abdominal pain. Patients taking the drug also may have neurologic symptoms such as insomnia, restlessness, paresthesias, twitching, polyneuritis, and even seizures. In 2020, the FDA approved nifurtimox for the treatment of Chagas disease in pediatric patients (birth to less than age 18 years).

There is broad agreement that persons with advanced symptomatic *T. cruzi* infection should not be given specific treatment. An enduring question is whether adults with long-standing indeterminate-phase infections, who by far constitute the largest group of *T. cruzi*–infected persons, should be treated. In two studies of asymptomatic PCR-positive patients, treatment with benznidazole for a year suppressed parasitemias and resulted in a negative PCR in 90% of treated patients.[A1] Similar suppression was observed in another study in which adults with indeterminate Chagas disease were treated with 300 mg daily for 4 weeks, and no further advantage was evident with 8 weeks of therapy.[A2] However, there is no clear evidence from these or other previous studies that the suppression of parasitemias delays the onset of symptoms, slows the progression of disease, or reduces mortality.[A3]

Based on available data, individuals who were born in or lived in endemic areas of Mexico, Central America, and South America should be screened serologically.[19] Women determined to be positive but not currently pregnant should be treated with a full course of benznidazole with the goal of reducing the rate of congenital transmission to babies they may have, even years later.

Management of Symptomatic Chagas Disease

Patients who have newly diagnosed *T. cruzi* infection with symptomatic cardiac or gastrointestinal disease should be referred to appropriate specialists (Fig. 318-2). Treatment of acute and chronic Chagas disease (Chapter 47) is similar to managing such symptoms in patients with cardiomyopathy (Chapter 47), heart failure (Chapter 46), and arrhythmias (Chapters 51 to 53) from other causes.[20] Some data suggest that carvedilol (up-titrated to 25 mg twice daily) may reduce mortality in Chagas cardiomyopathy.[A4] Pacemakers are useful in patients with bradyarrhythmias. Combined endocardial and epicardial catheter ablation can significantly reduce ventricular arrhythmias,[A5] but the usefulness of implantable cardioverter-defibrillators in patients with recurrent ventricular tachycardia has not been clearly established.[21]

Heart transplantation (Chapter 46) is an option in patients with end-stage Chagas cardiac disease, and several hundred such patients have undergone the procedure in Argentina, Brazil, and the United States. As is the case with other *T. cruzi*–infected patients who are immunosuppressed, reactivation is a risk but is manageable with standard treatment protocols.[22] The usefulness and side effects of prophylaxis for reactivation with benznidazole in *T. cruzi*–infected patients after heart transplantation is being evaluated. The long-term survival of Chagas patients with heart transplants appears to be longer than that of patients undergoing cardiac transplantation for other reasons, probably because the lesions of *T. cruzi*–associated pathology affect mostly the heart.

Chagas megaesophagus should be treated similarly as for idiopathic achalasia (Chapter 124), which usually responds to balloon dilation of the lower esophageal sphincter when symptoms are mild. Peroral endoscopic myotomy may be required in patients who do not respond to repeated attempts at balloon dilation.[23]

Chagas megacolon in its early stage can be treated with a high-fiber diet and occasional laxatives or enemas. Fecal impaction may require manual disimpaction, and toxic megacolon requires surgery. In patients with advanced megacolon, volvulus (Chapter 128) can develop when an enlarged and lengthened sigmoid colon twists and folds on itself; volvulus causes a constellation of symptoms and in many cases requires immediate surgery. Even if the symptoms associated with volvulus are resolved without operative intervention, however, surgical treatment is usually ultimately necessary because the volvulus tends to recur. Several surgical procedures to treat advanced Chagas megacolon require resection of the sigmoid and removal of part of the rectum.

PREVENTION

Reducing human contact with triatomine vectors through education of at-risk persons, improved housing, and spraying of residual insecticides (which kill insects that land or crawl on surfaces) in endemic countries has reduced or eliminated the vector transmission of *T. cruzi* in a major part of the endemic range, and progress in this regard is expected to continue. Serologic screening of donated blood has essentially eliminated transfusion-related transmission of the parasite in most endemic areas. Outbreaks of acute Chagas disease through oral transmission can be avoided by the implementation of better food safety standards. Drug treatment of *T. cruzi*–infected women before pregnancy reduces the likelihood of congenital transmission. No protocols have been defined and validated for preventing reactivation of *T. cruzi* infection in chronically infected persons who are immunosuppressed iatrogenically or by HIV. A treatment regimen that reliably results in parasitologic cure is needed to prevent the onset or progression of chronic symptomatic Chagas disease.

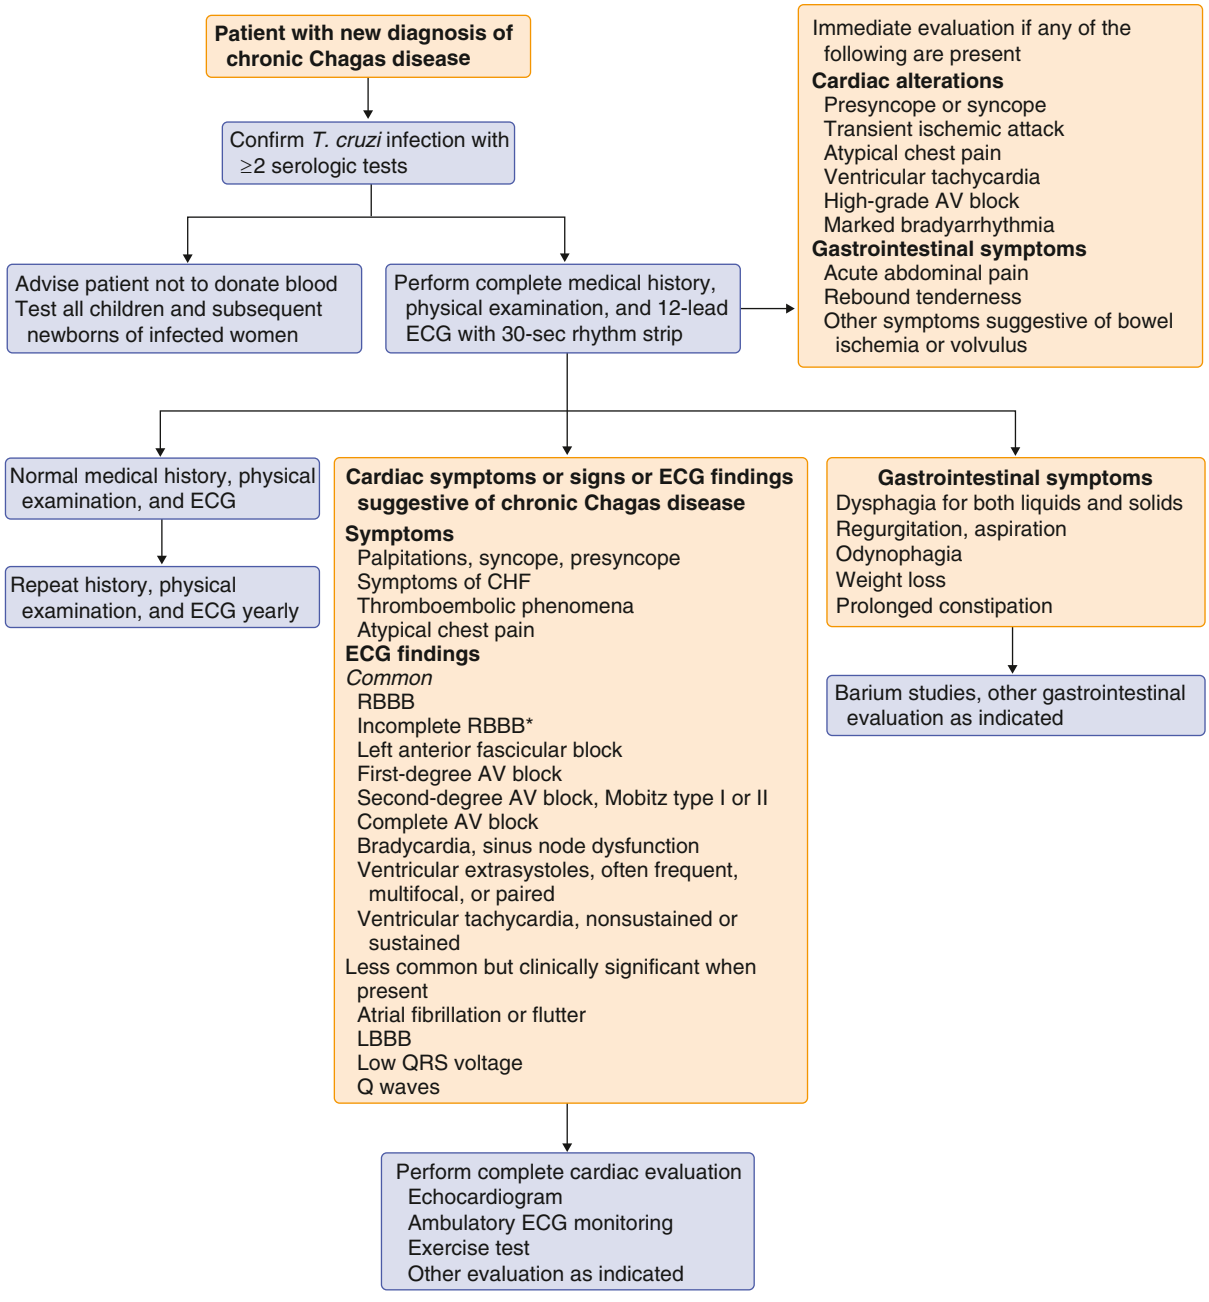

FIGURE 318-2. **Algorithm for baseline evaluation of a patient with newly diagnosed chronic *Trypanosoma cruzi* infection.** *QRS interval of 0.10 to 0.11 seconds in adults. Criteria based on the *Minnesota Code Manual of Electrocardiographic Findings* with modifications from Maguire et al. Different criteria may be required for ECGs in children. PROGNOSIS

For acute Chagas disease, the prognosis is generally excellent because most acutely infected persons have only mild symptoms that resolve spontaneously, even without specific treatment. However, the reported mortality rate for foodborne acute Chagas disease may be as high as 1%.[24] The occasional patient who has symptomatic acute Chagas myocarditis should generally do well if treated early.

For chronic *T. cruzi* infection, mortality is not increased for chronically seropositive individuals without cardiomyopathy,[25] and the lifetime risk for the development of related cardiac or gastrointestinal dysfunction is only 10 to 30%. A validated risk score assessment tool can estimate prognosis in the absence of heart transplantation (Table 318-2).

319 LEISHMANIASIS

PIERRE A. BUFFET, SIMON L. CROFT, AND MITALI CHATTERJEE

DEFINITION

Leishmaniasis, which is caused by protozoan parasites of the genus *Leishmania*, is generally transmitted between mammalian hosts by female phlebotomine sandflies. The parasite exists as an extracellular flagellated form, the promastigote, in the gut of the female sandfly, and as an intracellular form, the amastigote, in the phagolysosomal compartment of macrophages in the mammalian host. The disease in humans affects either the skin/mucosae or internal organs and ranges in severity from a single, self-curing skin lesion to widespread multilesional cutaneous involvement, or a potentially fatal visceral disease that affects the spleen, liver, and bone marrow.

The Pathogen

Leishmaniasis is caused by 20 different species of *Leishmania*, which are widely distributed in Europe, Asia, Africa, and South and Central America, with foci in South East Asia.[1] *Leishmania* are unicellular eukaryotic protozoa with a well-defined nucleus and 36 chromosomes. *Leishmania* exist in two forms. In the promastigote form in the alimentary tract of the sandfly, it is an extracellular, motile organism with a long flagellum. In its amastigote form in mammals, it is found in mononuclear phagocytes, where it is intracellular, is nonmotile, and lacks a flagellum. *Leishmania* are 1 to 3 μm in breadth in mammals compared with 15 to 30 μm in length and 5 μm in width in the sandfly. The kinetoplast and basal body lie towards the anterior end.

EPIDEMIOLOGY

An estimated 1.0 million clinical cases of leishmaniasis occur each year, but this number is probably an underestimate because leishmaniasis is not a reportable disease in many of the endemic countries and territories where it is known to occur.[2]

Infection is established in the mammalian host following a bite of the female sandfly belonging to either *Phlebotomus* spp in Europe, Asia, and Africa or *Lutzomyia* spp in the Americas. Different species of sandfly are associated with transmission of different *Leishmania* species. Most leishmaniasis is caused by 12 species (Table 319-1). Most species that cause cutaneous leishmaniasis are acquired from another mammal (zoonotic transmission cycle), with the exception of *Leishmania tropica*, which is frequently transmitted between human beings (anthroponotic cycle). Visceral leishmaniasis is usually anthroponotic (in the case of *Leishmania donovani*) or zoonotic (in the case of *Leishmania infantum*). The predominant mammalian hosts (the reservoirs) are associated with different *Leishmania* species in diverse ecosystems (Fig. 319-1).

Visceral leishmaniasis is caused by either *L. donovani* or *L. infantum* (which is identical to *Leishmania chagasi* in South America). These species have different geographic distributions, with the highest incidence found in the poorest communities in eight countries (India, Sudan, South Sudan, Ethiopia,

ABSTRACT

Leishmaniasis, which is caused by protozoan parasites of the genus *Leishmania,* is transmitted by sandflies. The 20 species of *Leishmania* are widely distributed in Europe, Asia, Africa, and South and Central America, with limited foci in South East Asia. The predominant mammalian hosts (the reservoirs) are associated with different *Leishmania* species in diverse ecosystems. The disease in humans affects either the skin/mucosae or internal organs, and it ranges in severity from a single, self-curing, limited skin lesion to widespread multilesional cutaneous involvement, and from a single lymphadenopathy to potentially fatal visceral disease affecting the spleen, liver, and bone marrow. An estimated 1 million new cases of cutaneous and 30,000 cases of visceral leishmaniasis occur annually in 82 and 93 countries, respectively. Visceral leishmaniasis is caused by either *Leishmania donovani* or *Leishmania infantum*. The highest incidence is found in the poorest communities of India, Sudan, South Sudan, Ethiopia, Eritrea, and Brazil. Since 2005, the annual incidence has declined by more than 90% in South East Asia (India, Bangladesh, Nepal). Diagnostic confirmation of visceral leishmaniasis is generally made by the rK39 dipstick, but alternative approaches include visualization of Leishman Donovan bodies on splenic or bone marrow aspirates, polymerase chain reaction testing, or serology. Treatment of visceral leishmaniasis is based on liposomal amphotericin B at most foci but is more complex in East Africa and challenging in immunodeficient patients. Cutaneous leishmaniasis self-cures in 20 to 90% of patients within 3 to 18 months, and treatment is usually by local measures.

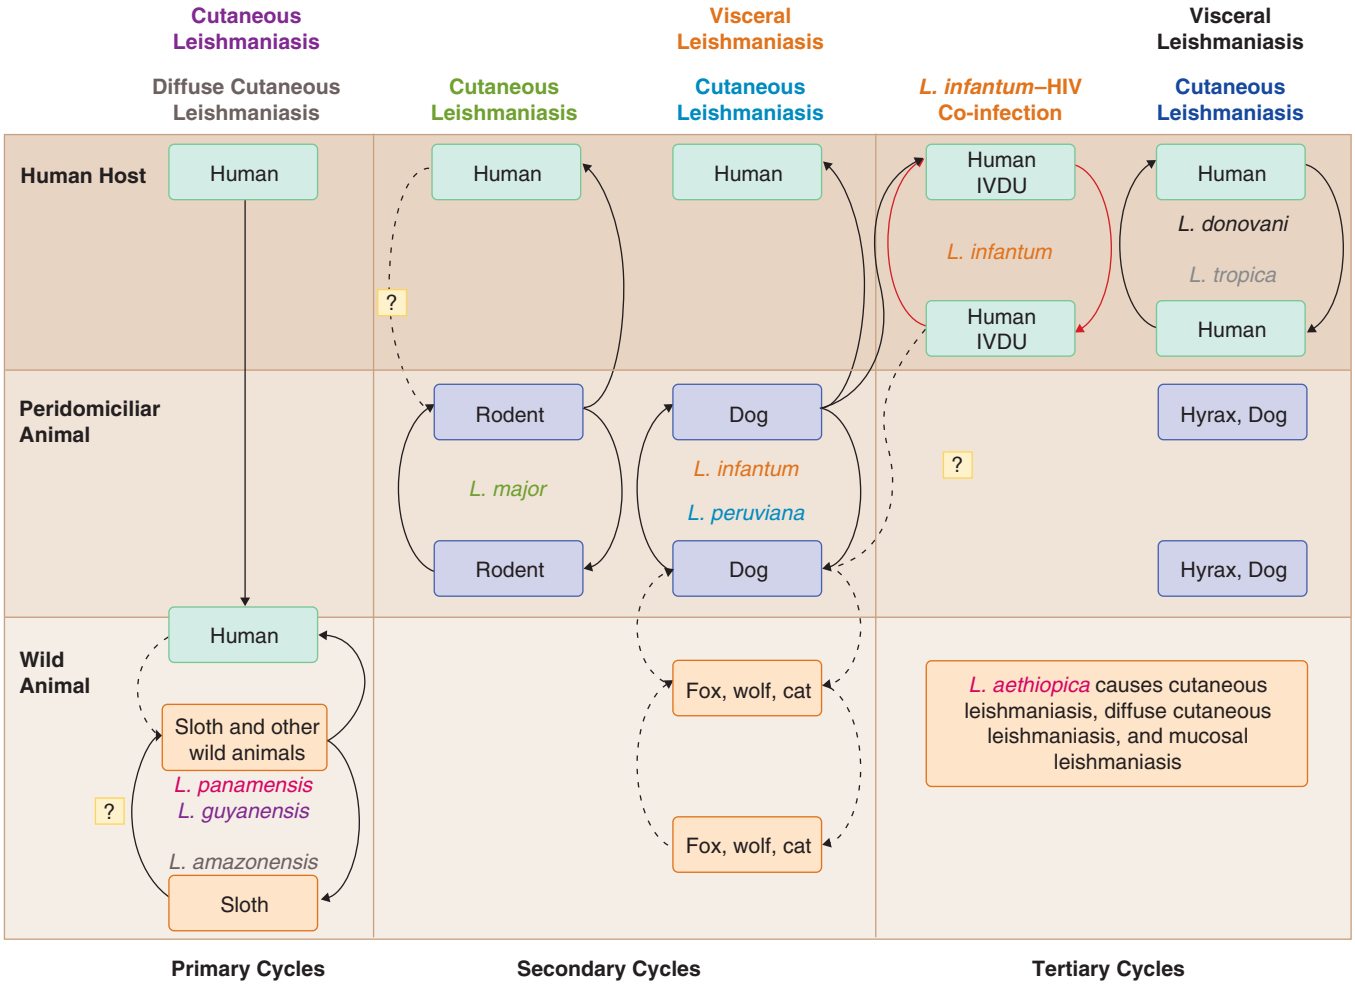

FIGURE 319-1. **Old World and New World zoonotic and anthroponotic life cycles of the main species of *Leishmania*.** Leishmaniasis is often referred to as a "disease complex" because different forms of disease can be caused by the same parasite species and similar forms of disease can be caused by different parasite species. HIV = human immunodeficiency virus; IVDU = intravenous drug use.

Eritrea, Somalia, Kenya, and Brazil). An estimated 1 in 5 to 1 in 50 infections are symptomatic, depending on the parasite species and host immunity. Since 2005, an initiative in South East Asia has reduced the annual incidence of the disease by more than 90%, but the economic burden of infection remains enormous.[3]

Cutaneous leishmaniasis is widely distributed, but its prevalence is difficult to estimate because of underreporting. Leishmaniasis is more common in children under age 16 years and in working-age men, but is uncommon in persons over age 65 years. This age prevalence may be related to the acquisition of immunity and to risk factors, including the presence of domestic animals, rodents, or other mammalian hosts. Ecologic conditions for sandflies, including shaded and humid habitats in crevices and mammal burrows, have been identified. Urbanization, deforestation, and migration have resulted in changing patterns of disease, with transmission occurring in peridomestic cycles. Other forms of transmission, such as through organ transplantation, blood transfusion, intravenous needles shared by drug users, transplacental or perinatal passage, or laboratory exposure, have been reported.

PATHOBIOLOGY

The infection is initially established in the skin after the inoculation of infective metacyclic promastigotes by the sandfly. These infective forms have a glycoprotein coat (a lipophosphoglycan) that enables them to resist complement and attach to and invade host cells. Peptides in the saliva of sandflies (e.g., maxadilan) cause vasodilatation and erythema and help establish infection in the dermal layer of the skin. Early responses to infection involve neutrophilic infiltration and invasion of resident macrophages. Progress of the disease depends on the parasitic species and the host response. For both visceral leishmaniasis and cutaneous leishmaniasis, progression of the disease depends on the maintenance of a parasite-specific immunosuppressive state. During established disease, host cell macrophages polarize from a classic (M1 phenotype) to a nonclassic, alternatively activated (M2 phenotype). Following successful treatment, macrophages become classically activated and are then able to kill the intracellular parasites, which are sensitive to nitric oxide and oxygen radicals, in the phagolysosomal compartment. After the activation of macrophages, resolution of disease is enhanced by a helper T-cell type 1 (T_H1) response following interaction between antigen-presenting cells (e.g., dendritic cells) with $CD4^+$ and $CD8^+$ T cells, as well as subsequent secretion of pro-inflammatory cytokines (e.g., interleukin-12 [IL-12], interferon-γ, tumor necrosis factor-α). In clinical forms such as active visceral leishmaniasis or diffuse cutaneous leishmaniasis, a mixed T_H1/T_H2 cell response occurs with the latter predominating, and downregulation of macrophage activity follows the production of cytokines such as IL-4, IL-10, IL-13, and transforming growth factor-β.[4]

In patients with visceral leishmaniasis, the absence of a T-cell-specific immune response to leishmanial antigens is associated with uncontrolled progression of infection. Progression is linked to elevated levels of IL-10 and decreased production of interferon-γ. Genetic susceptibility to *L. donovani* in Sudan has been associated with a solute carrier family that regulates the activation of macrophages and with a polymorphism in the IL-4 gene.

In localized simple cutaneous leishmaniasis, patients show a T_H1-type response and a delayed-type hypersensitivity response. Chronic infections show a T_H2-type response, most predominantly in patients with diffuse cutaneous leishmaniasis, in whom there is complete anergy to *leishmania* antigen and no delayed-type hypersensitivity response. Patients with mucosal leishmaniasis have a T_H1 or T_H2 cell response or both, and they also have a strong or weak delayed-type hypersensitivity response.

Post–kala-azar dermal leishmaniasis, which is a rare sequela after cure of visceral leishmaniasis, is seen in two geographically distinct zones, the Sudanese/East African form and the South East Asian form. The Sudanese and South

East Asian forms differ in that the former appears along with visceral leishmaniasis (para–kala-azar dermal leishmaniasis), whereas the latter appears 1 to 5 years later (post–kala-azar dermal leishmaniasis), The presence of alternatively activated M2 macrophages and a predominant CD8 T-cell milieu have been identified in the South East Asian form, whereas the immunopathology remains poorly defined in the Sudanese form.

VISCERAL LEISHMANIASIS

CLINICAL MANIFESTATIONS

Leishmania infection can be asymptomatic in about 11% of the population in endemic areas, and many cases are not diagnosed until several months after the onset of symptoms.[5] The onset of visceral leishmaniasis, previously referred to as kala-azar when caused by *L. donovani,* occurs weeks to months after the initial infection. Clinical signs and symptoms, such as fever and hepatosplenomegaly, do not definitively distinguish visceral leishmaniasis from other infectious or hematologic conditions. Moderate to severe anemia, mild to moderate leukopenia, thrombocytopenia, systemic inflammation, and polyclonal hypergammaglobulinemia, either isolated or combined, suggest but do not confirm the diagnosis. Parasitologic tests are therefore indispensable before making a therapeutic decision.[6]

DIAGNOSIS

Polymerase chain reaction (PCR) is more sensitive than microscopic examination and is the first-line diagnostic test when it is available.[7] Quantitative PCR with a kinetoplast DNA target and validated thresholds allows accurate diagnosis with venous blood.

Microscopic visualization of amastigotes in samples from the lymph nodes, bone marrow, liver, spleen, or other organs is an option if PCR testing is not available. Splenic aspiration should be performed only in trained facilities and only if other, lower risk methods cannot be used. Parasites also occasionally can be found in the blood or urine.

Antigen-based tests have a high specificity but only moderate sensitivity and are not widely used, except in patients who are infected with the human immunodeficiency virus (HIV). Serologic tests to detect *Leishmania* antibody have high diagnostic accuracy but require equipment that is poorly adapted to field settings. Specific antibodies remain detectable for several years after asymptomatic infection or cure.

COMPLEX MANIFESTATIONS OF VISCERAL LEISHMANIASIS

VISCERAL LEISHMANIASIS–HUMAN IMMUNODEFICIENCY VIRUS COINFECTION

In patients who have visceral leishmaniasis and who are infected with HIV but who do not have severe immunosuppression, the clinical manifestations are generally similar to those in immunocompetent patients. In patients who have low $CD4^+$ T-cell counts (<200/μL), however, classic signs (e.g., splenomegaly) may be absent. A substantial proportion of patients coinfected with *Leishmania* and HIV may have other opportunistic infections that complicate the clinical diagnosis. The parasitic load is usually higher, and parasites may be found in tissues other than spleen, liver, bone marrow, or lymph nodes (e.g., gut or lung), especially in severely immunosuppressed patients. As a result, the sensitivity of microscopic examination, culture, or PCR of blood (whole blood or buffy coat) or bone marrow aspirates is generally higher than that in immunocompetent patients with visceral leishmaniasis. Limited data have also shown high sensitivity of the latex agglutination based antigen testing in coinfected patients but not of antibody testing. Increased sensitivity can be achieved by using a sequential combination of different serologic tests.

POST–KALA-AZAR DERMAL LEISHMANIASIS

After successful treatment of visceral disease due to *L. donovani,* some patients in Sudan and South East Asia progress to widespread cutaneous disease.[8] In Sudan, the skin lesions appear concomitantly during visceral leishmaniasis in 50% of cases. In South East Asia, however, skin lesions appear in 5 to 10% cases of visceral leishmaniasis about 2 to 10 years after apparent cure. With active case surveillance,[9] these proportions of post–kala-azar dermal leishmaniasis have been increasing. In a very small proportion of patients with post–kala-azar dermal leishmaniasis, uveitis occurs with poor visual prognosis. PCR testing is more sensitive than smears in macular cases. Serologic tests are of limited value because a positive finding may be the result of persistent antibodies following a past episode of visceral leishmaniasis, but they can be helpful when a previous history of visceral leishmaniasis is uncertain.

TREATMENT

General Principles

The therapeutic management of patients with visceral leishmaniasis requires re-nutrition, broad-spectrum antibiotics if bacterial superinfection is suspected, transfusion in cases of severe anemia, and proper hydration, especially when amphotericin B is used for the specific antileishmanial treatment.

The clinical response to antileishmanial agents depends on the clinical form, the infecting species and subspecies (zymodeme), and geography. Many antileishmanial agents are toxic, expensive, or difficult to administer in field conditions, but they can be administered on an outpatient basis in developed countries.[9] No single satisfactory option for treating most of the clinical forms or species has been validated.

In nonendemic and some endemic countries, treatment of visceral leishmaniasis is based on liposomal amphotericin B,[10] but treatment is more complex in East Africa and in some endemic countries where liposomal amphotericin B is less effective.[11] Expert advice is typically required for relapsing visceral leishmaniasis in immunocompromised patients, as well as for cutaneous leishmaniasis or mucosal leishmaniasis.

Visceral Leishmaniasis in Immunocompetent Patients

Single-Agent Therapies

Liposomal amphotericin B, which is the first-line option in most nonendemic countries, cures 100% of patients at 30 days and 96% of patients at 6 months in South East Asia with a single infusion of 10 mg/kg; it is recommended in the national program to eliminate visceral leishmaniasis. In East Africa, the doses of liposomal amphotericin B required to cure visceral leishmaniasis (30 to 50 mg/kg cumulatively) are markedly higher than in India, and the drug fails in about 20% of patients, even with these higher doses. Liposomal amphotericin B is not adequately effective to treat post–kala-azar dermal leishmaniasis.[12] Amphotericin B (cumulative dose of 7 to 15 mg/kg) cures more than 98% of patients in India, whereas treatment of visceral infection with *L. infantum/chagasi* requires at least 14 mg/kg (generally 21 mg/kg cumulative dose over 10 days).

Pentavalent antimonials (sodium stibogluconate, meglumine antimoniate) are still prescribed as first-line therapy in many areas outside of Southeast Asia, where resistance is high. In other locations, failure rates of initial treatment do not exceed 10% if patients are treated with the correct dose (20 mg/kg/day of pentavalent antimony for 28 days). In an endemic country, mortality in treated patients may exceed 10%, with toxicity positively correlating with age. Pentavalent antimonials are contraindicated in patients with heart, kidney, or liver disease or advanced age and in pregnant women. Generic formulations have not consistently demonstrated activity and tolerance identical to that of sodium stibogluconate.

Miltefosine (an oral alkyl phosphocholine at 2.5 mg/kg/day for 28 days) is very effective for visceral leishmaniasis in South East Asia. In Ethiopian patients with visceral leishmaniasis (28% with HIV infection), miltefosine is more effective than generic sodium stibogluconate (98% survival vs. 90% survival). Miltefosine is contraindicated in women who are pregnant or may become pregnant. Due to the drug's terminal elimination half life of 30 days, contraceptive measures must be observed for more than 3 months after therapy. Abdominal pain, nausea, and vomiting are frequent adverse events, and rarely corneal disorders (especially in post–kala-azar dermal leishmaniasis) has been reported. For post–kala-azar dermal leishmaniasis, treatment remains to be clearly defined; presently, miltefosine (50 mg orally daily if <25 kg, 50 mg twice daily if >25 kg) administered orally for 12 weeks is preferred over liposomal amphotericin B.[A1]

Paromomycin (aminosidine sulfate) (15 mg/kg in sulfate form equivalent to 11 mg of base per kilogram intramuscularly for 21 days) is highly effective in India; however, its efficacy is significantly lower in East Africa, and it is used only in combination with other drugs. *Pentamidine* is efficient in treating visceral leishmaniasis only when high doses (more than seven injections of 4 mg/kg) are used. Such doses are sufficiently toxic[13] that pentamidine is no longer used for the initial treatment of visceral leishmaniasis. Lower doses (fewer than four injections of 4 mg/kg every 2 or 4 weeks) induce much fewer adverse events and are still used for the secondary prophylaxis of visceral leishmaniasis in HIV-infected patients.

Combinations/Coadministration

To limit extension of drug resistance, shorter courses of two drugs are potentially preferable to monotherapy. For example, combinations of amphotericin B plus oral miltefosine (sequential) or intramuscular paromomycin plus miltefosine can achieve cure rates of up to 98% with 7- to 10-day courses of therapy in East Africa. A single infusion of liposomal amphotericin B followed by oral miltefosine has been highly effective in India.

Visceral Leishmaniasis in Immunodeficient Patients

As with other major opportunistic infections during HIV infection, treatment may be subdivided into initial course and secondary prophylaxis. The potential risk for the widespread emergence of resistance to antileishmanial agents is more significant for *L. donovani,* which (unlike *L. infantum*) can be transmitted by sandflies from humans to humans.

For initial treatment, the efficacies of pentavalent antimonials and amphotericin B are similar, but the dose is higher than in immunocompetent patients

(40 mg/kg in cumulative dose). Patients benefit from effective antiretroviral treatment (Chapter 357). If HIV patients remain immunocompromised, secondary prophylaxis with amphotericin B lipid complex (1 mg/kg monthly) moderately reduces the frequency of recurrences. Miltefosine (50 mg three times per week) is another option, especially if the reduction in parasitic load is documented by quantitative PCR testing. Administration of pentamidine (monthly infusions of 4 mg/kg) once or twice a month is another potential option because drug levels persist for weeks or months after a single administration. Pancreatic tolerance should be monitored closely.

Liposomal amphotericin B 30 mg/kg plus miltefosine (usually 2 daily doses of 50 mg for 28 days) can achieve a higher initial cure rate than liposomal amphotericin B alone (40 mg/kg) for *L. donovani* in East Africa.[A2] However, the best strategy to reach sustained cure without relapse will require further research.

CUTANEOUS LEISHMANIASIS

CLINICAL MANIFESTATIONS

The clinical consequences of cutaneous leishmaniasis are dermatologic, and concomitant visceral impairment is very unusual. Although the signs and symptoms of cutaneous leishmaniasis vary considerably (Fig. 319-2)—from pure nodular lesions to developing ulceration through dry crusty lesions and squamous plaques—some features are fairly constant. First, firm infiltration is almost constant (the exception being the initial macule of post–kala-azar dermal leishmaniasis). Second, the evolution is subacute. A lesion that reaches its maximum size in less than a week is most likely not due to cutaneous leishmaniasis. Finally, except in patients with numerous satellite papulopustules, the lesion or lesions are sharply defined. Colonization of the cutaneous leishmaniasis ulcer with bacteria may give the lesion a purulent appearance, whereas true superinfection adds an erythematous ring distinctly overflowing the infiltrated edge of the ulcer, and transforms a usually cold and painless lesion into a hot and painful lesion.

The intensity of the discomfort, related to one or several oozing or unsightly lesions, and the impact of atrophic, hypopigmented, or hyperpigmented scars depend on the lesions' topography. In the New World, mucosal impairment may affect up to 1 to 15% of patients, with greater incidence in Bolivia. Tegumentary infection with *Leishmania infantum* may also spread to mucosae in up to 20% of patients.

DIAGNOSIS

Several dermatologic conditions such as staphylococcal (Chapter 267) or streptococcal (Chapter 269) infection, mycobacterial ulcer (Chapters 299 and 300), leprosy (Chapter 301), fungal infection, cancer, sarcoidosis (Chapter 83), and tropical ulcer mimic cutaneous leishmaniasis or mucosal leishmaniasis lesions (see Fig. 319-2). Diagnostic confirmation is necessary because treatment is costly and potentially toxic.

Parasitology

Scraping, fine-needle aspiration, or biopsy of lesions provides appropriate samples in which amastigotes can be identified, more easily on smears or imprints (cytology) than on tissue sections (histology) (Fig. 319-3). Scraping should be performed under local anesthesia at both the center and edges of the lesion with a curved scalpel blade. The 2- to 4-mm skin fragment obtained by punch biopsy provides abundant material, which facilitates the search for scarce parasites and for an alternative diagnosis by culture. PCR testing, which is preferred if available, enables the identification of the specific *Leishmania* species in regions where several *Leishmania* species coexist.

Microscopic examination of Giemsa-stained material is the most widely available method.[14] Serologic diagnosis is of limited use for cutaneous leishmaniasis because of low sensitivity.

COMPLEX MANIFESTATIONS OF CUTANEOUS LEISHMANIASIS

MUCOSAL LEISHMANIASIS

A proportion of cutaneous leishmaniasis infections (about 1 to 10% in South America) caused by *Leishmania braziliensis* or *Leishmania guyanensis* progress to a metastatic infection of the mucosa of the oral/nasal cavity or larynx, often 1 to 5 years after healing of the initial simple cutaneous lesion. Mucosal infection has also been reported in travelers returning from endemic countries[15] in South America or, more recently, in southern and western Europe where this complication of *Leishmania infantum* infection is often associated with underlying immunosuppression.[16] Immunopathology shows extensive destruction of local tissue. Allergic rhinitis (Chapter 394), paracoccidioidomycosis (Chapter 308) or other deep mycosis (Chapter 312), leprosy (Chapter 301), cancer and sarcoidosis (Chapter 83) may mimic the lesions of mucosal leishmaniasis. Positive serology or leishmanin skin testing indicates possible mucosal leishmaniasis. Parasites are scarce in mucosal lesions, so a search for parasites by microscopy in mucosal scrapings or biopsy has a poor sensitivity, but PCR testing of scraping or biopsy material has a high sensitivity.

DIFFUSE CUTANEOUS LEISHMANIASIS

Patients with diffuse cutaneous leishmaniasis have an anergic response to *Leishmania* antigens. This form of the disease is found in South America and East Africa, often associated with *Leishmania amazonensis* and *Leishmania aethiopica* infection. Nonulcerative nodules, loaded with parasites, disseminate from the initial site of infection to multiple skin sites. There is no self-cure, and treatment is difficult.

TREATMENT

The risk for metastasis (affecting the nose or less frequently other otorhinolaryngeal zones) has strongly influenced therapeutic decisions.[17] Although many patients with cutaneous leishmaniasis cure spontaneously within 3 to 18 months, local therapy[A3] with intralesional injections of pentavalent antimonials[18] (preferentially following a brief application of liquid nitrogen),[A4] photodynamic therapy,[A5] and thermotherapy are attractive options (Fig. 319-4). However, implementation of these methods is hampered by logistic constraints and requires skilled health care providers. Paromomycin ointment is efficacious and well tolerated for cutaneous leishmaniasis caused by several species in North Africa and Central America and in travelers.[A6]

Topical liposomal amphotericin B gel also may be tried.[A7] When local treatment cannot be administered or fails, systemic therapy is used. Oral therapy with relatively nontoxic drugs (e.g., fluconazole 200 to 600 mg/day for 42 days,[A8] or miltefosine 2 to 2.5 mg/kg/day for 28 days[A9]) is the simplest option, but no optimal drug regimen has been solidly validated. In cutaneous leishmaniasis caused by *L. guyanensis* or *Leishmania panamensis*, low doses of pentamidine (1 to 3 intramuscular injections of 7 mg/kg every 72 hours or preferably a slow intravenous infusion in dextrose) generally cure more than 75% of patients.[A10] The efficacy of systemic liposomal amphotericin B in cutaneous leishmaniasis is markedly lower than in visceral leishmaniasis, and it presently is not considered an adequate first-line option. Inadequate surgical excision or excessive doses of systemic parenteral treatments, especially without sufficient follow-up, may carry more risk than benefit for patients with cutaneous leishmaniasis.[19]

RECIDIVANS CUTANEOUS LEISHMANIASIS

Recidivans cutaneous leishmaniasis is characterized by the development of lesions containing granulomatous tissue. The lesions often require many years to heal and may arise years after healing of a simple localized lesion. New ulcers and papules may form over the edge of the old scar. Infections are normally associated with *L. tropica* infection and are difficult to treat.

DISSEMINATED CUTANEOUS LEISHMANIASIS

Disseminated cutaneous leishmaniasis is characterized by the presence of more than 10 lesions in more than two distant sites. It has been described in Brazil and is associated with a higher risk of mucosal involvement. The same term is used to describe multilesional involvement in immunosuppressed patients generally infected with *L. infantum*.

PREVENTION

No vaccines or prophylactic drug regimens are currently available.[20] Sandflies are sensitive to most insecticides, so transmission may be reduced by residual spraying in houses. Insecticide-impregnated bed nets and dog collars (to prevent transmission of zoonotic cutaneous leishmaniasis) have been investigated. Personal permethrin-impregnated clothing is protective against cutaneous leishmaniasis.

PROGNOSIS

Most untreated patients with established visceral leishmaniasis ultimately die, but the death rate is less than 2% in patients treated early with liposomal amphotericin B. Mortality increases when bleeding (mainly from the digestive tract or lung) or secondary bacterial infection occurs, usually after prolonged untreated evolution or unresponsiveness of visceral leishmaniasis to first-line agents. Post-therapeutic relapse is very frequent in HIV-coinfected patients with initially or persistently low $CD4^+$ counts. In immunosuppressed patients, visceral leishmaniasis contributes to a fatal outcome. A proportion of *L. donovani*–infected patients experience post–kala-azar dermal leishmaniasis weeks to years after the initial episode, sometimes complicated by severe ocular involvement.

FIGURE 319-2. Clinical features of cutaneous leishmaniasis. A, Typical forms of cutaneous leishmaniasis. **A1**, Papular-nodular. **A2**, Squamous. **A3**, Crusty. **A4**, Ulcerated. **A5**, Superinfected lesions. **B**, Atypical forms of cutaneous leishmaniasis and mucosal leishmaniasis. **B1**, Multiple papules on the face (*L. infantum*, Balearic islands). **B2**, Nodular lymphangitis (*L. braziliensis*, Brazil). **B3**, Multiple lesions with numerous peripheral papules (*L. major*, Tunisia). **B4**, Initial spread to the nasal mucosa (anterior septum, *L. braziliensis*, Bolivia). **B5**, Infiltration and ulceration of the tonsils (*L. infantum*, France). **C**, Clinical manifestations that are not cutaneous leishmaniasis. **C1**, Multiple papules (late secondary syphilis) (Chapter 295). **C2**, Nodular lymphangitis (sporotrichosis) (Chapter 308). **C3**, Single crusty ulceration (*Mycobacterium ulcerans* infection) (Chapter 300). **C4**, Ulcerated acute *Staphylococcus aureus* infection (Chapter 267). **C5**, Ulcerated nodule keratoacanthoma (Chapter 188).

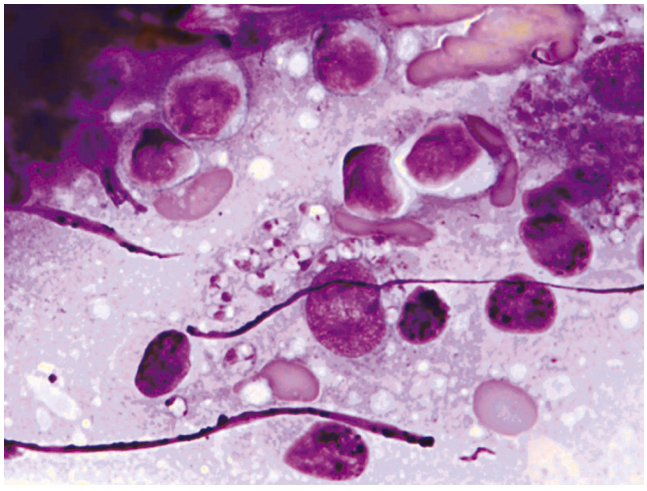

FIGURE 319-3. **Amastigotes of *Leishmania major* in scrapings from a skin ulcer.**

Cutaneous leishmaniasis undergoes self-cure in 20 to 90% of patients within 3 to 18 months, depending on the infecting species and the geographic location. Cutaneous leishmaniasis caused by *L. braziliensis, L. guyanensis,* and *L. infantum* may metastasize to the nose and other mucous membranes with variable frequency in different areas. Cutaneous leishmaniasis caused by *L. tropica* often relapses (recidivans cutaneous leishmaniasis). A small proportion of patients infected with *L. amazonensis* and *L. aethiopica* experience diffuse cutaneous leishmaniasis. Even when treated, many cutaneous leishmaniasis lesions leave disfiguring, hypotrophic, hypopigmented, or hyperpigmented scars that can be stigmatizing.

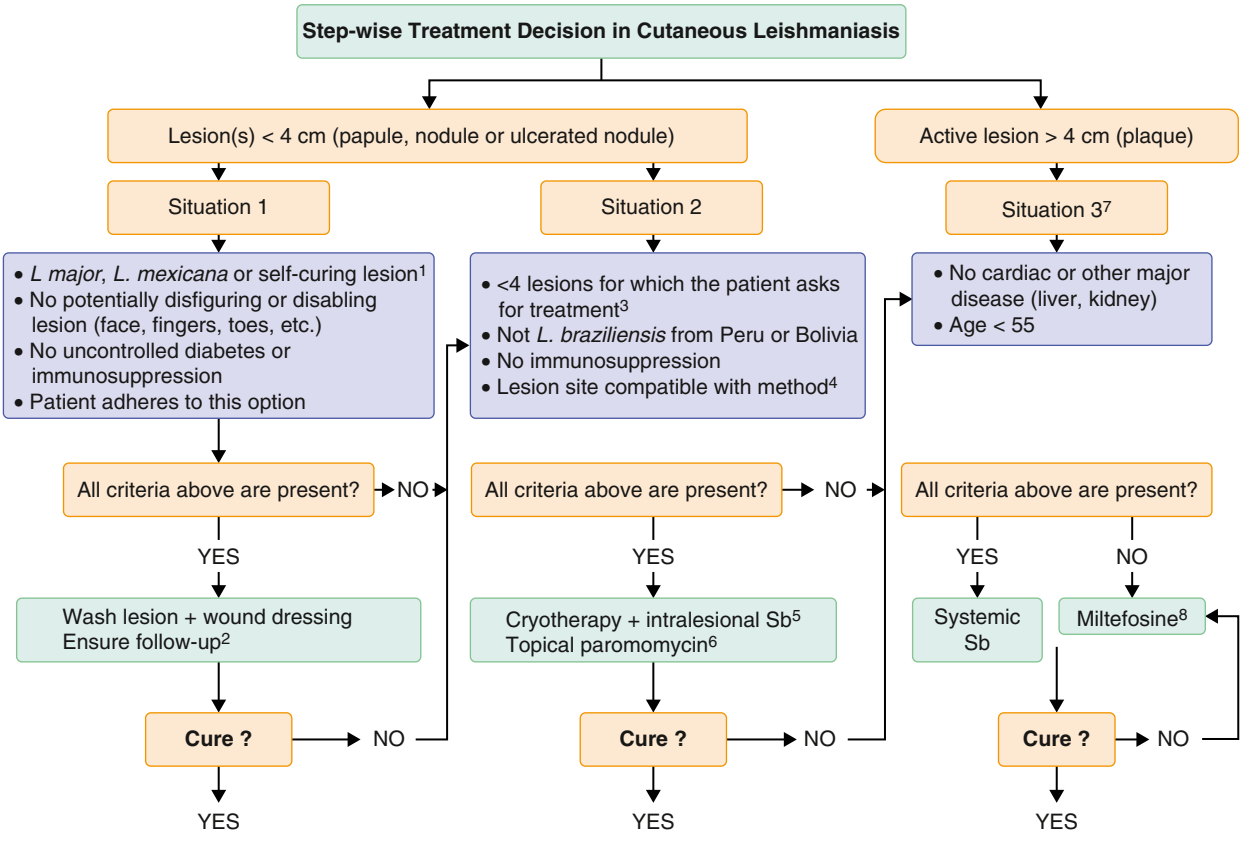

FIGURE 319-4. **Algorithm of treatment options for cutaneous leishmaniasis—an example of decision making.** (1) Self-curing lesions show flattening or reduction in the surface of the ulceration and/or induration. (2) Washing lesion, wound dressing, and follow-up performed in all situations. (3) Lymphatic dissemination in itself does not influence treatment decisions, except when it increases the number of lesions requiring therapy. (4) Most lesions of limbs, trunk, cheek, upper cheek, chin, and face can be injected, including those close to large joints. Injection in ears, fingers, and toes is very painful. (5) When/where cryotherapy is not available, simpler physical methods can be adopted. (6) In 2022, the validated formulation of topical paromomycin is available only through clinical trials or compassionate use. (7) In case of pregnancy, wait until after delivery or use liposomal amphotericin B. (8) Miltefosine should be used with caution or dose adaptation (or both) in patients with liver or kidney involvement or with gastrointestinal symptoms. Sb = pentavalent antimony.

320 TOXOPLASMOSIS

ANITA A. KOSHY

DEFINITION

Toxoplasmosis refers to symptomatic disease, whereas *T. gondii* infection refers to latent, asymptomatic disease. *Toxoplasma gondii* is a ubiquitous protozoan parasite. Although felids are *T. gondii*'s only definitive host (i.e., where parasitic sexual reproduction occurs), the parasite's intermediate hosts include most warm blooded animals, from birds to humans. In both the definitive and intermediate hosts, *T. gondii* causes an acute infection followed by the establishment of a long-term persistent or latent infection. The initial acute infection can be symptomatic, but *T. gondii* is predominantly known for causing congenital disease in children of mothers with a primary infection during pregnancy and encephalitis in persons with severe acquired immune deficiencies.

The Pathogen

T. gondii has a sexual and asexual life cycle. During the sexual life cycle, which occurs in felid enterocytes, the parasite differentiates into male and female gametocytes, which fuse to form a diploid zygote. This diploid form is surrounded by a protective wall, which collectively forms the unsporulated oocyst that is expelled into the environment via felid feces (Fig. 320-1A). After being expelled, the oocysts sporulate to form haploid sporozoites, which are infectious if ingested.[1] These oocysts, which are extremely hardy, can potentially survive for years in the environment. Felids apparently are the only definitive host because only their enterocytes have the excess levels of linoleic acid that are required for sexual reproduction owing to their lack of the delta-6-desaturase enzyme, which helps convert linoleic acid to arachidonic acid.[2]

In the asexual life cycle, which is subdivided into lytic and latent stages, *T. gondii* replicates its haploid genome and divides into two daughter cells via a process called endodyogeny, by which the two daughter cells form within the mother, and then the mother cell dissolves. During the lytic cycle, parasites are in a fast-replicating form called a tachyzoite (see Fig. 320-1B). As tachyzoites rapidly expand in number and disseminate throughout the body, they generate a robust immune response. As the immune response clears tachyzoites, the tachyzoites convert to bradyzoites, which are a slow-replicating form of *T. gondii* that forms tissue cysts in certain organs and cell types, especially neurons and striated muscle (see Fig. 320-1C). These tissue cysts, which can contain hundreds or even thousands of bradyzoites, typify the latent stage of the life cycle. At this stage, the organism can evade the host's immune system, thereby enabling long-term infection. This long-term latent infection is essential for passage of *T. gondii* between intermediate hosts,[3] a process thought to underlie *T. gondii*'s success as a parasite (geographically ubiquitous and with a broad intermediate host range).

EPIDEMIOLOGY

Humans become infected with *T. gondii* via the ingestion of undercooked meat that contains tissue cysts (both commercial and game) or oocyst-contaminated water or food[4,5]; vertical transmission from mother to child; rarely from solid organ transplantation; and potentially from transfusions. Infection from a cat occurs when oocysts or cat feces contaminate food or water, or when caretakers use poor hand-hygiene when exposed to cat feces (i.e., cleaning kitty litter). Thus, risk of infection depends on a variety of parameters such as cultural habits (e.g. having cats as pets, drinking unpasteurized goat's milk) and access to clean water and hygiene, which often correlate with geography and socioeconomic status.

As estimated by seropositivity surveys, rates of infection with *T. gondii* vary in different countries and within a single country. For example, although the overall U.S. seropositivity rate is estimated to be about 11%,[6] the seropositivity among the Old Order Amish in Lancaster County, Pennsylvania is over 50%.[7] Similarly, people living in the former East Germany have a higher *T. gondii* seroprevalence than people who live in the former West Germany, a distinction that is postulated to arise from the East German tradition of eating raw minced beef and pork. In developed nations, *T. gondii* seroprevalence is higher in rural populations compared with urban populations; but in Brazil, urban populations have a higher seroprevalence. Although seropositivity often increases with age, presumably owing to increased exposure over a lifetime, high levels of seropositivity are seen even at a young age in urban areas in Brazil.[8]

In the era before highly active anti-retroviral therapy, approximately 30 to 50% of patients who were seropositive for human immunodeficiency virus (HIV) and had the acquired immunodeficiency syndrome (AIDS) developed toxoplasmic encephalitis, but that risk is now very low in patients who are on effective therapy. Both primary and reactivation disease has been seen in patients who are taking immunosuppressive drugs (e.g., anti-TNF therapy, rituximab, and mycophenolate mofetil), but these risks are relatively rare compared with HIV/AIDS patients with low CD4 counts.[9]

Patients who undergo hematopoietic stem cell transplants (Chapter 163) or solid organ transplantation are at risk for toxoplasmosis. The risk of toxoplasmosis is highest for allogenic hematopoietic stem cell transplants when the recipient is seropositive for toxoplasmosis and the donor is seronegative; in this situation, the recipient has a high likelihood of latent *T. gondii* infection, but the donor's immune system lacks preexisting adaptive immunity to *T. gondii*.[10] For recipients of solid organ transplants, the risk of symptomatic toxoplasmosis is just the opposite—highest when the recipient is seronegative but the donor is seropositive. The risk is highest in recipients of heart transplants, presumably because heart tissue is known to harbor persistent, encysted parasites. For other solid organ transplants,[11] infection can be seen clinically months to years after transplantation, when it is difficult to determine whether the parasite came from the transplanted organ or whether the recipient developed a symptomatic primary or reactivation infection because of long-term immunosuppression.

Congenital toxoplasmosis most commonly occurs when a seronegative pregnant woman develops a primary infection. The likelihood of transmitting the infection to the fetus increases with gestational age, with a 6% or less risk for maternal seroconversion at less than 13 weeks of gestation and above 70% risk for seroconversion at 36 weeks or more. Infections in early gestation have a higher likelihood of severe infection compared to late infections. Mother-to-child infection is unusual in HIV patients who have a CD4 count above 200 cells/μL.

The genotype of the infecting *T. gondii* strain may also influence the severity of the primary infection in an immunocompetent host as well as vertical transmission of congenital disease and ocular infection in immunocompromised patients. Limited data from congenitally infected infants and their parents also suggest that human polymorphisms in *nalp1/nlrp1* and *alox12* may play a role in susceptibility to congenital toxoplasmosis. The mechanisms by which these polymorphisms contribute to this susceptibility are unknown, but differences in NLRP1-triggered pyroptosis determine the likelihood of *T. gondii* infection in different strains of rats.

PATHOBIOLOGY

In postnatally acquired infection, most individuals become infected with *T. gondii* by ingesting either tissue cysts or oocysts. Once ingested, bradyzoites or sporozoites are released via digestive enzymes, followed by infection of epithelial cells. During this enteral stage, parasites convert to the tachyzoite stage, which disseminates throughout the body. The innate and adaptive immune response targets the tachyzoites, thereby controlling the infection in a manner that is highly dependent upon the production of interferon (IFN-γ) by immune cells, especially $CD8^+$ effector T cells, and subsequent IFN-γ responses in hematopoietic and nonhematopoietic cells.[12] Key innate immune cells include the antigen presenting dendritic cells, natural killer cells, neutrophils, tissue-infiltrating monocytes, and tissue macrophages such as microglia.[13]

In the face of this stress, tachyzoites transition to encysting bradyzoites, which are not fully cleared from specific organs (e.g., eye, brain) thereby leading to long-term persistence. In hosts who become immunocompromised and occasionally even in immunocompetent individuals, these persistent parasites reactivate to cause symptomatic disease. The conversion to the bradyzoite/encysted stage, which includes changes in the parasite's surface antigens, is thought to help parasites evade the tachyzoite-directed immune response. Although the human immune response to bradyzoites/cysts may be muted, some degree of a bradyzoite-directed immune response probably does occur.[14]

Human Pathology Findings

Biopsies of *T. gondii*–infected lymph nodes show nonsuppurative lymphadenitis with reactive follicular hyperplasia, uneven clusters of epithelioid histiocytes/cells that blur germinal center margins, and monocytoid B lymphocytes in focally distended sinuses. Toxoplasmic encephalitis typically causes multiple focal necrotizing (untreated) or organized abscesses (treated), but a more diffuse necrotizing form also can be seen. Pulmonary toxoplasmosis can cause interstitial pneumonitis, consolidation, empyema, or a combination of these pathologies. Ocular toxoplasmosis commonly presents as a focal, full-thickness,

ABSTRACT

Toxoplasmosis is the symptomatic disease caused by the ubiquitous protozoan parasite *Toxoplasma gondii*. *T. gondii* is a common parasitic infection that causes a long-term, generally asymptomatic infection that can reactivate in the immunocompromised. The major organs in which *T. gondii* persists are the skeletal and cardiac muscle and the central nervous system (especially the brain and retina). In immunocompetent individuals, acute *T. gondii* infection can cause lymphadenitis, chorioretinitis, and rarely more severe infections. Congenital infection and infection in immunocompromised patients can lead to life-threatening disease, most commonly with brain manifestations. Universal screening is recommended in all pregnant women. A positive polymerase chain reaction test or detection of toxoplasma tachyzoites in any bodily fluid is diagnostic. Common treatment regimens are trimethoprim-sulfamethoxazole, pyrimethamine (plus folinic acid) plus sulfadiazine, clindamycin, or atovaquone. With early treatment, outcomes are generally good, but congenital infection is associated with a high rate of miscarriage and severe malformations.

chorioretinitis, with or without scars, and it also can be fulminant with panophthalmitis and even orbital cellulitis in immunocompromised hosts. Rare reports of myocarditis and myositis also show focal necrosis.

CLINICAL MANIFESTATIONS

T. gondii infections cause a wide range of symptoms, which vary from acute as compared with chronic infection and are different in immunocompetent individuals as compared with immunocompromised patients or patients with congenital infection (Table 320-1).

Infection in Immunocompetent Patients (Including Pregnant Women)

Patients who are acutely infected with *T. gondii* typically experience a mild febrile illness that is similar to infectious mononucleosis (Chapter 348) and is commonly associated with lymphadenopathy (Chapter 154), fatigue, headaches, and myalgias.[15] In the non-outbreak setting, most immunocompetent individuals do not know when they became infected with *T. gondii*.

In Latin America (Brazil, French Guiana, Suriname), small numbers of immunocompetent patients have experienced atypically severe acute infections, including multiorgan failure, pneumonia, and death. Most of these patients have been males who ate raw or undercooked game or drank potentially contaminated water, and they often were infected by *T. gondii* strains that appear to be more virulent than the common strains seen in the U.S. and Europe.

The frequency of acute ocular toxoplasmosis in immunocompetent patients varies by setting (outbreak vs. non-outbreak) and country. In the United States, an estimated 21,000 patients will develop ocular disease, but only about 5000 of these cases are symptomatic. Ocular symptoms include blurred vision, loss of vision (scotoma or central vision if the macula is involved), pain, and tearing. Some patients who present with what seems to be an acute infection already have retinal scars in non–vision affecting areas, thereby suggesting they are having a reactivation event rather than a new acute infection.

Rare cases of acute encephalitis have been reported in apparently immunocompetent patients. Although retrospective reports have suggested an association between *T. gondii* seropositivity and a wide range of mental and neurologic diseases, no substantial or convincing evidence links *T. gondii* infection to these noninfectious psychiatric or neurologic conditions.

Infection in Immunocompromised Patients

Patients with HIV/AIDS or on Immunosuppressive Medications

Encephalitis is the most common manifestation of toxoplasmosis in HIV/AIDS patients whose CD4 count drops below 100 cells/μL. These patients can present with nonspecific symptoms, such as lethargy and altered mental status, as well as focal abnormalities such as hemiparesis, cerebellar signs, or seizures.[16,17] The course is usually subacute over days to weeks, but acute presentations can occur.

Patients can also present with symptoms and signs of chorioretinitis, pneumonia, and rarely gastrointestinal or musculoskeletal symptoms. Immune reconstitution syndromes and *T. gondii* encephalitis rarely have been described when HIV/AIDS patients are treated and their CD4 counts rise to above 200 cells/μL. In the limited number of cases of toxoplasmosis in patients who have been on immunosuppressive drugs, encephalitis with multiple, ring-enhancing lesions has been the most common presentation.

Organ Transplantation

Both primary and reactivation toxoplasmosis can be seen in patients after organ transplantation; distinguishing between the two can be difficult and will not change management. The range of signs and symptoms includes fever, rash, lymphadenopathy, chorioretinitis, pneumonia, myocarditis, hepatosplenomegaly, rash, toxoplasmic encephalitis, and even sepsis.[18,19] Although toxoplasmic encephalitis in organ transplant recipients can present as the typical ring-enhancing lesion (i.e., abscess-like), cases of diffuse infiltration also have been reported. In these patients, a suspicion for toxoplasmosis must be based upon discordant serologies in the donor as compared with the recipient, absence of appropriate prophylaxis for a history of *T. gondii*, and other risk factors for exposures to *T. gondii*.

Congenital Infection

The signs and symptoms of congenital infection vary widely from spontaneous abortion to mild or severe disease. Severe congenital infection can present with a range of nonspecific symptoms such as petechial rash, splenomegaly,

TABLE 320-1 CLINICAL MANIFESTATIONS OF TOXOPLASMOSIS IN HUMANS

CLINICAL CATEGORIES	CLINICAL MANIFESTATIONS AND SYNDROMES
PRIMARY INFECTION	
Immunocompetent individuals	Most patients are asymptomatic or have a nonspecific flu-like febrile illness often with lymphadenitis. Acute chorioretinitis can present with blurred vision, loss of vision, pain, and tearing. Often the fundoscopic examination will show fluffy white, necrotizing chorioretinitis close to a pigmented chorioretinal scar. Rare cases of acute multiorgan failure, pneumonia, hepatitis, myocarditis, myositis, and death have been reported, primarily in Latin America.
Immunocompromised host (e.g., solid organ transplant recipient)	Encephalitis/focal brain abscess, pneumonia/pneumonitis, chorioretinitis, multiorgan involvement, hepatitis, renal failure
CHRONIC INFECTION	
Immunocompetent individuals	Most persons with chronic toxoplasmosis are asymptomatic. Reactivation of chorioretinitis can occur in congenitally or postnatally acquired disease.
Reactivation in immunocompromised patients, including seropositive recipients of a stem cell transplantation from a seronegative host	Multiple brain abscesses, diffuse encephalitis, seizures, chorioretinitis, fever of unknown origin, pneumonia, myocarditis, hepatosplenomegaly, lymphadenopathy, rash
CONGENITAL TOXOPLASMOSIS	
Fetus	Ultrasound study can be normal or reveal hydrocephalus, brain or hepatic calcifications, splenomegaly, ascites, pericarditis. Infection can also result in spontaneous abortion.
Newborn	Newborn can be normal or have nonspecific signs, symptoms, or findings, including CNS calcifications, microphthalmia, chorioretinitis, seizures, abnormal cephalic perimeter (microcephaly or hydrocephalus), hepatomegaly, splenomegaly, petechial rash, thrombocytopenia, or anemia.
Children and adults	Children can continue to suffer from chronic sequelae such as psychomotor retardation, seizures, and vision loss. Asymptomatic infants may be become symptomatic during childhood, adolescence, or adulthood, with the most common manifestation being chorioretinitis.

CNS = central nervous system.
Modified from Montoya JG. Toxoplasmosis. In: Goldman L, Schafer A, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020.

hepatomegaly, brain calcifications, chorioretinitis, microphthalmia, microcephaly, hydrocephalus, and prematurity. Given the nonspecific nature of these signs and symptoms, other common causes of congenital infection must be excluded (e.g., syphilis [Chapter 295], rubella [Chapter 339], cytomegalovirus [Chapter 347], herpes simplex [Chapter 345], Zika virus [Chapter 352]), although the constellation of chorioretinitis, hydrocephalus, and brain calcifications should raise the suspicion for toxoplasmosis. In the absence of treatment, even infants who appear asymptomatic at birth can develop symptoms such as chorioretinitis as they grow older.

DIAGNOSIS

The most common tests used to diagnose *T. gondii* include serology, polymerase chain reaction (PCR) testing, and histopathology (Table 320-2). For most scenarios, especially in immunocompetent patients, the first step is serology because negative serologic testing (both immunoglobulin [Ig]-M and IgG) makes *T. gondii* highly unlikely. PCR is very specific but its sensitivity, especially in immunocompetent patients, can be low.[20] Except for lymphadenitis, for which histopathology is very specific, most patients require a positive specific test such as *T. gondii*–specific immunohistochemical or fluorescent

TABLE 320-2 LABORATORY METHODS FOR THE DIAGNOSIS OF *TOXOPLASMA GONDII* INFECTION AND TOXOPLASMOSIS* IN HUMANS

METHOD	CLINICAL INTERPRETATION
Serologic tests	
IgG	A positive test result establishes that the patient has been infected with *T. gondii*. However, a negative test result can be seen in patients infected within 4 weeks before serum sampling or in patients unable to produce IgG (e.g., immunocompromised hosts).
IgM	A positive test result suggests but is not necessarily diagnostic of an acute infection. Sera with positive IgM test results should be sent to a reference laboratory for confirmatory testing that includes a more specific IgM assay and additional tests, including avidity, acetone (AC)-fixed versus formalin (HS)-fixed (AC/HS) differential agglutination test of tachyzoites, and IgA and IgE.† Positive IgM test results can be seen in chronically infected patients because of persistence of the IgM response or false-positive results observed in certain commercial kits.
Confirmatory testing for positive IgM test results	IgG avidity test; differential agglutination (AC/HS); IgA, IgE performed at a reference laboratory.† A high IgG avidity test result‡ or a nonacute AC/HS test result indicates that the patient has been infected for more than 4 mo (avidity) or 12 mo (AC/HS).
Polymerase chain reaction (PCR)	The B1 gene and the 529-bp repetitive element are the most common gene targets for amplification. PCR test can be performed in any body fluid, including amniotic fluid, peripheral blood, cerebrospinal fluid, bronchoalveolar lavage fluid, vitreous fluid, aqueous humor, peritoneal fluid, pleural fluid, ascitic fluid, and urine. PCR can also be performed in any tissue. A positive test result in any body fluid establishes that the patient has either acute or reactivated toxoplasmosis. However, a positive PCR test result in tissue is more difficult to interpret because it does not differentiate symptomatic toxoplasmosis from a latent infection. Although DNA extraction is more cumbersome, it can be done in paraffin-embedded tissue.
Direct visualization of the parasite	Identification of tachyzoites in any body fluid or tissue is diagnostic of toxoplasmosis due to acute infection or reactivation of a chronic infection. Tachyzoites can be identified by hematoxylin and eosin or cytologic studies but are better visualized with Wright-Giemsa and immunoperoxidase stains. Identification of cysts by hematoxylin and eosin or immunoperoxidase stains confirms the presence of *T. gondii* in the host but does not necessarily establish that the patient has toxoplasmosis.
Attempts to isolate the parasite	A positive isolation study in any body fluid establishes the diagnosis of toxoplasmosis. Isolation of *T. gondii* in cell cultures or peritoneal cavity of mice can be attempted at reference laboratories. These studies can be important in trying to establish a correlation between the genetics of the parasite and its clinical manifestations.
Histology of the lymph node	Classic histologic triad is considered diagnostic: nonsuppurative lymphadenitis with reactive follicular hyperplasia, uneven clusters of epithelioid histiocytes that blur germinal center margins, and monocytoid B lymphocytes in focally distended sinuses.
Fundoscopic examination	Unilateral, focal infection showing fluffy white, necrotizing chorioretinitis with vitritis (sometimes with a pigmented chorioretinal scar) can be associated with anterior uveitis, vasculitis, and optic neuritis (though involvement of the optic nerve is relatively rare)

**T. gondii* infection = asymptomatic presence of the parasite. Toxoplasmosis = active symptoms and signs are present.
†For example, https://www.sutterhealth.org/services/lab-pathology/toxoplasma-serology-laboratory; remingtonlab@sutterhealth.org or (650) 853-4828
‡The window of exclusion for acute infection varies for different avidity kits (usually between 3 and 5 months).
bp = base pairs; Ig = immunoglobulin; PCR = polymerase chain reaction.
Modified from Montoya JG. Toxoplasmosis. In: Goldman L, Schafer A, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020.

staining. Because many healthy individuals have latent *T. gondii* infection, caution must be exercised to ensure that *T. gondii* is the causative agent rather than an incidental finding, especially in atypical clinical scenarios.[21] Evidence of an active infection includes a positive PCR test on blood, cerebrospinal fluid (CSF), or aqueous fluid; identification of tachyzoites on histopathology; or robust inflammation around a cyst.

Immunocompetent Patients

Diagnosing acute or active toxoplasmosis in the immunocompetent individual is essential but complicated for several reasons: the frequency of latent *T. gondii* infections; the fact that *T. gondii* IgM can be positive for 1 to 2 years post-infection; the tendency for non-reference laboratories to have a higher rate of false positive IgM testing; and the nonspecific symptoms of acute toxoplasmosis. Distinguishing between acute and chronic infection is extremely important in situations in which a tissue diagnosis is difficult to obtain or in pregnant women, in whom the likelihood of fetal infection and need for prenatal treatment is often determined by the acuity of the infection. In these scenarios, expert consultation and advanced testing, such as IgG avidity,[22] should be obtained from a reference laboratory.

Immunocompromised Patients

In immunocompromised patients, the diagnosis of toxoplasmosis is based on a positive PCR test on fluid (e.g., CSF, bronchial alveolar lavage, peripheral blood) or tissue or by identifying an active *T. gondii* infection via a histopathologic study. In patients undergoing stem cell or heart transplantation, who are at the highest risk, routine monitoring of peripheral blood by PCR for *T. gondii* parasitemia may permit diagnosis before patients become sick.

Ocular Toxoplasmosis

The diagnosis of ocular toxoplasmosis is commonly initially made when an ophthalmologist's fundoscopic examination shows fluffy white necrotizing chorioretinitis close to a pigmented chorioretinal scar (Fig. 320-2 and see Table 320-2).[23] Primary infection is suspected when no old scars are identified in either eye, whereas the presence of such scars would suggest reactivation disease. Serologic confirmation by IgG plus IgM in the blood of patients who have acute or chronic *T. gondii* infection is important because a negative serology essentially excludes ocular toxoplasmosis except in rare severely immunocompromised patients. If the fundoscopic examination is atypical but the concern is high, anterior chamber or vitreous fluid can be tested for parasitic DNA by PCR or IgM and IgG antibody levels in the eye fluid can be compared with serum antibody levels. Such testing should be done in consultation with physicians with expertise in diagnosing ocular toxoplasmosis.

Toxoplasmic Encephalitis in HIV/AIDS Patients

Brain imaging with contrast will often show multiple ring-enhancing lesions (Fig. 320-3), with magnetic resonance imaging (MRI) being more sensitive than computed tomography (CT). In HIV/AIDS patients who have CD4 counts below 200 cells/μL and a positive *T. gondii* IgG, the presence of multiple ring-enhancing lesions on CT or MRI establishes a presumptive diagnosis of toxoplasmic encephalitis and requires empirical treatment. Patients who improve clinically within 7 days are presumed to have toxoplasmic encephalitis, though caution must be exercised in patients who are also prescribed corticosteroids (for cerebral edema) because the reduction in edema and/or response of CNS lymphoma to corticosteroids can lead to clinical improvement in the absence of toxoplasmosis.

If, however, the patient shows clinical progression within 3 days, does not improve by 10 to 14 days, or has evidence of progression/new lesions on brain imaging, then further evaluation is required. Similarly, patients who have a single enhancing lesion on MRI or CT or whose *T. gondii* IgG is negative also require further evaluation. This evaluation can be pursued by CSF cytology and PCR (to test for *T. gondii*, Epstein-Barr virus, JC virus [Chapter 341], mycobacteria [Chapters 299 and 300], and cryptococcus [Chapter 309]). Stereotactic brain biopsy is an alternative, which is indicated if the patient deteriorates or does not appropriately improve over 10 to 14 days. For HIV/AIDS patients whose *T. gondii* is thought to be causing pneumonia or myositis, the diagnostic approach is to obtain PCR or biopsy on an appropriate fluid or tissue.

Congenital Toxoplasmosis: Prenatal and Postnatal Diagnosis

If an acute infection is documented or highly suspected in a pregnant woman, fetal ultrasound and PCR on amniotic fluid can determine if the fetus has been infected. Finding brain calcifications or hydrocephalus on a fetal ultrasound can suggest acute fetal infection but generally is not diagnostic. A positive PCR on amniotic fluid is essentially 100% specific for confirming fetal infection, but its sensitivity ranges from 60 to 90%, with the higher sensitivity when performed between 17 and 21 weeks of gestational age.

Congenital toxoplasmosis is confirmed in the setting of a persistent positive IgG, IgM taken at or after 5 days of age, and/or a positive IgA taken at or after 10 days of age. Brain imaging showing calcifications and hydrocephalus can also confirm the diagnosis. Given the complexity of diagnosing congenital toxoplasmosis and its implications for treatment, expert consultation is highly recommended in these situations.

TREATMENT

Immunocompetent Patients

Most patients with acute toxoplasmosis are asymptomatic or have transient nonspecific symptoms that resolve without treatment. For patients with lymphadenopathy or lymphadenitis (Chapter 154) most cases will resolve without any intervention, though enlarged lymph nodes can persist for more than 6 months. One month of trimethoprim-sulfamethoxazole leads to a faster resolution of symptoms and serologies compared with placebo. For patients who have more concerning symptoms suggestive of visceral organ involvement, treatment (Table 320-3) for 2 to 4 weeks followed by re-assessment may be appropriate.

Immunocompromised Patients

The preferred primary regimen for immunocompromised patients is pyrimethamine, sulfadiazine, and folinic acid (see Table 320-3). Trimethoprim-sulfamethoxazole is an easier alternative, especially in resource-limited regions of the world, although aggregate data suggest it may be slightly less effective.[A1] In HIV/AIDS patients who are not yet on anti-retroviral treatment, immediate initiation of both anti-retroviral therapy and anti-toxoplasma therapy is no more likely to trigger the immune reconstitution syndrome than is delayed toxoplasmosis treatment.[A2]

Ocular Toxoplasmosis

For ocular toxoplasmosis, systemic treatment is required, as for acute infection (see Table 320-3) based on whether the patient is immunocompetent or immunosuppressed, because of the potential loss of vision.[A3,A4] However, treatment also includes subconjunctival, topical, or intravitreal treatments under the direction of an ophthalmologist. An active recurrent unilateral ocular lesion in an immunocompetent patient should be treated with double-strength trimethoprim-sulfamethoxazole (1 dose twice daily for 45 days, followed by 1 dose every other day for 1 year).[A5]

Pregnant Women with Acute Infection

To reduce the likelihood of maternal-to-child-transmission, the usually recommended approach has been to initiate treatment as soon as possible, and ideally within no more than 3 weeks after maternal infection, with spiramycin (which is not teratogenic) for maternal infections occurring before 14 weeks of gestation (Table 320-4).[24] The combination of pyrimethamine plus sulfadiazine plus folinic acid is slightly more effective and, in at least in one trial, was equivalently safe,[A6] so this combination is probably preferred. Unfortunately, spiramycin does not cross the placenta. If fetal infection is confirmed (by amniotic fluid PCR) or highly suspected by fetal ultrasound, treatment should be pyrimethamine, sulfadiazine, and folinic acid (see Table 320-4) after 14 to 18 weeks of gestational age.[25] Whether to use this regimen earlier is controversial, with recommendations varying among experts. Postnatal treatment should be provided to infants with toxoplasmosis by their pediatricians.

TABLE 320-3 TREATMENT REGIMENS FOR PATIENTS WITH ACUTE OR PRIMARY TOXOPLASMOSIS AND IMMUNOCOMPROMISED PATIENTS WITH TOXOPLASMOSIS DUE TO REACTIVATION*

	IMMUNOCOMPETENT PATIENTS WITH ACUTE INFECTION†	IMMUNOCOMPROMISED PATIENTS
A. Pyrimethamine and folinic acid‡ (PO)	100 mg daily for 1-2 days, followed by 25-50 mg daily	200 mg loading dose, followed by 50 mg/day (<60 kg) to 75 mg/day (>60 kg)
	10-20 mg daily (during and 1 wk after therapy with pyrimethamine)	10 to 25 mg daily (up to 50 mg daily or twice daily; during and 1 wk after therapy with pyrimethamine)
	Plus either sulfadiazine, clindamycin, or atovaquone as follows:	*Plus sulfadiazine (preferred), or clindamycin (preferred for sulfa allergic or poor response to pyrimethamine/sulfadiazine), or atovaquone*
PLUS		
Sulfadiazine (PO)	1000 mg every 6 hr	1000 mg (≤60 kg) to 1500 mg (>60 kg) every 6 hr
or		
Clindamycin (PO or IV)	300 mg every 6 hr	600 mg every 6 hr
or		
Atovaquone** (PO)	1500 mg orally twice daily	1500 mg orally twice daily
or		
B. Trimethoprim-sulfamethoxazole (PO or IV)	5-10 mg/kg/day (trimethoprim component) in two doses	TMP 5 mg/kg/day and SMX 25 mg/kg/day twice daily
or		
C. Pyrimethamine and folinic acid *plus* azithromycin (PO)	Same doses as above 250 to 500 mg/day (for severe systemic disease consider 1000 mg/day)	

*Preferred regimens: pyrimethamine, sulfadiazine, and folinic acid.

†Particularly in the setting of myocarditis, myositis, hepatitis, pneumonia, brain or skin lesions, and lymphadenopathy accompanied by severe or persisting symptoms. Also indicated for those with active ocular disease due to primary infection or reactivation.

‡Folinic acid = leucovorin; folic acid is not an appropriate substitute for folinic acid.

**Atovaquone 1500 twice daily also can be used on its own or with sulfadiazine.

In immunocompromised patients, the combination regimen for the acute or primary therapy phase is for 6 weeks, with the extent of primary treatment dependent on the clinical and radiologic extent of disease and response. The chronic maintenance dose regimens can be found at: https://clinicalinfo.hiv.gov/en/guidelines/adult-and-adolescent-opportunistic-infection/toxoplasma-gondii-encephalitis.

PREVENTION

Primary infection

Given that most persons will be infected with *T. gondii* by ingesting food, water, or unpasteurized milk that is contaminated with oocysts or by ingesting undercooked meat that contains tissue cysts, interventions to stop *T. gondii*

TABLE 320-4 TREATMENT REGIMENS FOR PREGNANT WOMEN WHO HAVE LIKELY ACQUIRED *TOXOPLASMA GONDII* INFECTION DURING GESTATION

	DURING PREGNANCY
Spiramycin (oral)	Recommended for pregnant women suspected of having or confirmed to have acquired the infection during gestation and before 14 weeks' gestation. Spiramycin should be administered until delivery in those with negative amniotic fluid PCR test results and normal follow-up ultrasound studies or low suspicion of fetal infection. Spiramycin is not teratogenic, and it is available in the United States only through the Investigational New Drug (IND) process at the Food and Drug Administration (301-796-1400). Dosage: 1 g (3 million units) every 8 hr (for a total of 3 g or 9 million units per day)
Pyrimethamine (oral) plus sulfadiazine (oral) plus folinic acid† (oral)	Recommended for women >14 weeks' gestation in whom it is suspected or confirmed that the acute infection has been acquired at or after 14 weeks' gestation or who have a positive amniotic fluid PCR test result or an abnormal ultrasound study suggestive of congenital toxoplasmosis Pyrimethamine is teratogenic and should not be used during pregnancy before week 14 (in some centers in Europe, it is used as early as week 14). Sulfadiazine should not be used alone. Dosages: Pyrimethamine: 100 mg daily for 2 days followed by 50 mg daily Sulfadiazine: 1000 mg q8h (<80 kg) or 1000 mg q6h (≥80 kg) Folinic acid† (leucovorin): 10-20 mg daily (during and for 1 wk after pyrimethamine therapy)

†Folic acid is not an appropriate substitute for folinic acid.

CSF = cerebrospinal fluid; PCR = polymerase chain reaction.

Modified from Montoya JG. Toxoplasmosis. In: Goldman L, Schafer A, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020.

infection should be targeted to these exposures. Women of child-bearing age should be careful to ensure hand hygiene and to avoid any exposure to cat feces.[26] For seronegative pregnant women, prenatal care should include focused education about preventing *T. gondii* exposure and periodic serologic screening starting at 11 weeks of gestation and continuing throughout pregnancy, with prompt (within 3 weeks) treatment of presumed new infections (see Table 320-4). Overall data suggest that these interventions have led to a decline in congenital toxoplasmosis.[27]

Prevention of Reactivation

Transplantation

All donors and recipients of stem cells and of all solid organ transplants must be screened for *T. gondii* via serology. In donor positive/recipient negative heart transplantation patients, prophylaxis with trimethoprim-sulfamethoxazole one double-strength tablet three times/per week for the remainder of their lives is highly recommended. For other solid organ transplant recipients, the evidence for prophylaxis is less clear, but most patients receive trimethoprim-sulfamethoxazole for 6 to 12 months.[28] In hematopoietic stem cell transplant donor negative/recipient positive transplantations, trimethoprim-sulfamethoxazole prophylaxis (one double-strength tablet 3 times per week) is usually started after engraftment because of the drug's bone marrow suppressive effects. For other stem cell recipients, treatment is usually based on the prevention of pneumocystis pneumonia (Table 313-2). Highly immunosuppressed patients who are at risk for acute toxoplasmosis also should be educated about how to avoid exposure to *T. gondii*.

HIV/AIDS and Other Immunosuppressed Patients

Reactivation Disease in Immunosuppressed Patients

Because of the relatively frequent development of toxoplasmic encephalitis in HIV/AIDS patients with decreased CD4 cell counts, HIV/AIDS patients with CD4 counts less than 100 cells/μL should receive daily prophylaxis with double-strength trimethoprim-sulfamethoxazole (160 mg/800 mg daily), which is also effective prophylaxis for *Pneumocystis jiroveci* (Chapter 313). Daily dapsone (50 mg) plus weekly pyrimethamine (50 mg) and leucovorin (25 mg) or weekly dapsone (200 mg), pyrimethamine (75 mg), and leucovorin (25 mg) are the preferred options for those who are intolerant to trimethoprim-sulfamethoxazole, although atovaquone (1500 mg) daily with or without daily pyrimethamine (25 mg) and folinic acid (10 mg) is also an accepted alternative. Prophylaxis should be stopped if the CD4 count rises to above 200 cells/μL for 3 or more months. For patients who are on long-term immunosuppressive therapy such as corticosteroids, the same regimen or one double-strength trimethoprim-sulfamethoxazole tablet 3 times weekly should be prescribed.

PROGNOSIS

The prognosis for *T. gondii* infection depends on many factors, but especially on the patient's immune status and potentially the genotype of the infecting *T. gondii* strain. Most immunocompetent patients who acquire *T. gondii* postnatally will be asymptomatic, and essentially all others will have their symptoms resolve, even without treatment. However, serious complications such as a permanent decrease in visual acuity or very rarely death can occur when patients develop symptomatic ocular toxoplasmosis or deep-seated organ infection (primarily seen in Latin America). In both congenital infection and immunosuppressed patients, the prognosis varies with extent of infection and rapidity of diagnosis and treatment. For all transplant patients, the development of symptomatic toxoplasmosis carries a significant risk of morbidity and mortality.[29] In severely immunocompromised patients, disseminated toxoplasmosis can frequently lead to permanent neurologic sequelae or death even with appropriate care.

321 CRYPTOSPORIDIOSIS

CIRLE A. WARREN AND ALDO A.M. LIMA

DEFINITION

Cryptosporidiosis is the disease in humans and animals caused by protozoal parasites of the genus *Cryptosporidium* (phylum Apicomplexa). *Cryptosporidium* spp are major waterborne parasites worldwide, and more than 20 species have been documented to infect humans.[1]

The Pathogen

The family Cryptosporidiidae has a hidden sporocyst and undergoes monoxenous completion of its cycle in one host, where it can cause predominantly intestinal, cloacal, and gastric infections. The life cycle begins with ingestion of *Cryptosporidium* oocysts (2 to 5 μm) by the vertebrate host, with subsequent excystation within the lumen of the small intestine to release four sporozoites (Fig. 321-1). Polarized sporozoites cells harbor the apical secretory organelles typical for *Apicomplexa* species, including micronemes, dense granules, and a single rhoptry. The sporozoites move probably by using the canonical glideosome, which is dependent on actin and myosin, and attach to and enter the host's epithelial cells to form intracellular but extracytoplasmic parasitophorous vacuoles, where they develop into trophozoites and subsequently type 1 meronts (schizonts).[2] This interface suggests that the *Cryptosporidium* is dependent on the host's metabolism. The parasite uses glycolysis fermentation as its sole source of energy. By asexual nuclear division, schizonts multiply and release six to eight type 1 merozoites that invade neighboring host cells and develop into type 2 meronts, or trophozoites, to complete the asexual reproductive cycle. Type 2 meronts undergo two nuclear divisions and release four type 2 merozoites that can infect the host's cells and further develop into male (microgamont) or female (macrogamete) forms. Microgametes released from the microgamont can penetrate the macrogametes to form zygotes. Approximately 20% of the zygotes develop into thin-walled autoinfectious oocysts; some 80% become thick-walled oocysts, which are excreted in stool.

EPIDEMIOLOGY

Cryptosporidiosis is seasonal and related to precipitation and temperature fluctuations worldwide. Excystation of *C. parvum* increases in water temperatures up to 46° C (natural sunlight for 12 hours). *Cryptosporidium* spp can be found in wastewater, surface water, drinking water, reservoir water, groundwater, and swimming pool water.[3] In the United States from 2015 to 2019, *Cryptosporidium* spp accounted for about 85% of nearly 3000 cases in 155 outbreaks of diarrhea associated with treated recreational water.[4] In addition to exposure to treated recreational water, other significant outbreak exposures include contact with cattle and contact with infected persons in child-care settings.[5] Food-borne outbreaks also have been reported in association with contaminated apple cider, unpasteurized milk, chicken salad, vegetables, raw produce, and shellfish.

C. hominis and *C parvum* are responsible for over 90% of human infections. *C. hominis* is the dominant species in developing countries, whereas both *C. hominis* and *C. parvum* are the dominant species in industrialized nations. *C. hominis* is more commonly associated with clinical illness. Less common *Cryptosporidium* spp such as *C. meleagridis*, *C. felis*, *C. canis*, *C. viatorum*,

C. hominis and *C parvum* are responsible for over 90% of human infections. *C. hominis* is the dominant species in developing countries, whereas both *C. hominis* and *C. parvum* are the dominant species in industrialized nations. *C. hominis* is more commonly associated with clinical illness. Less common *Cryptosporidium* spp such as *C. meleagridis*, *C. felis*, *C. canis*, *C. viatorum*,

ABSTRACT

Cryptosporidiosis is caused by protozoal parasites of the genus *Cryptosporidium*. Infection is acquired by ingestion of water that is contaminated with *Cryptosporidium* oocysts, followed by completion of the parasite's life cycle in the intestinal mucosa and then by excretion of infectious oocysts in the environment, often thereby contaminating the supply of drinking water and recreational water facilities. Cryptosporidiosis often leads to self-limited diarrhea in immunocompetent hosts during outbreaks or travel exposure but to persistent diarrhea in immunocompromised adults in endemic settings. *Cryptosporidium* species have emerged as an important cause of diarrhea in recipients of solid organ or hematologic transplants. Detection of the parasite is improved by immunoassays and molecular techniques. Therapeutic and preventive interventions are limited, especially for immunocompromised hosts. Transmission of disease may be controlled by treatment of water supplies to inactivate oocysts in drinking and recreational water facilities.

and *C. muris* are largely seen in developing countries, and *C. ubiquitum*, *C. cuniculus*, and *C. chipmunk* genotype I are mainly seen in industrialized nations. *C. parvum* infection is associated with animal exposures, especially cattle and dogs, as well as residence in rural settings, whereas *C. hominis* infection is more common with daycare or child care and residence in urban settings.[6]

The prevalence of cryptosporidiosis varies by geographic region,[7] with the highest rates seen in children in developing countries, where it is one of the five pathogens (including norovirus, rotavirus, *Campylobacter* spp, and astrovirus) with the highest attributable burdens of diarrhea in the first year of life.[8] Cryptosporidiosis causes more than 48,000 annual deaths worldwide in children under 5 years of age.[9]

Cryptosporidiosis continues to be a significant cause of intestinal infection among individuals with human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) who are not on effective antiretroviral therapy (Chapter 358).[10] In resource-sufficient settings, cryptosporidiosis has emerged as an important cause of diarrhea among HIV-negative individuals who are recipients of either solid organ or hematopoietic stem cell transplants. The incidence of cryptosporidiosis is also high among recent international travelers (Chapter 265) and men who have sex with men.[11]

PATHOBIOLOGY

Cryptosporidium oocysts and sporozoites interact with host cells, in the processes of excystation, gliding motility, attachment, invasion, parasitophorous vacuole formation, intracellular maintenance, and host cell damage. Oocysts of *Cryptosporidium* spp use their cysteine and serine proteases and aminopeptidase for excystation in the upper part of the small bowel and release infective sporozoites that invade the mucosal epithelium and occasionally Peyer patch M cells, often extending to the terminal ileum and colon. The sporozoites secrete proteins from the apical organelles for locomotion and attachment. In immunocompromised patients, the organisms can be found throughout the gut, biliary tract, pancreas, and respiratory tract. Sporozoites and merozoites are internalized by similar invasion machinery and actin reorganization. Two classes of proteins, mucin-like glycoproteins and thrombospondin-related adhesive proteins, mediate adhesion of the parasite. The parasite uses proteases for the proteolytic processing of surface and apical complex proteins for invasion and for egress from the host cells. Entry into the host's cell occurs within 30 seconds and is dependent on the parasite's actomyosin cytoskeleton to enter host-derived bimembrane parasitophorous vacuoles in a unique intracellular but extracytoplasmic niche. Dense polymerized actin forms at the base fusion of the host-parasite bimembranes. Invasion of cells of the host leads to

displacement of the microvillous border, villous atrophy, blunting and crypt cell hyperplasia, and marked infiltration by lymphocytes, plasma cells, and some neutrophils into the lamina propria, with apoptosis of infected cells. The intestinal epithelial barrier function is disrupted by the effects of *Cryptosporidium* on tight junction proteins.[12] Upregulation of nuclear factor κB and the proinflammatory cascade causes secretory and mildly inflammatory diarrhea. Proinflammatory cytokines, such as tumor necrosis factor-α, interleukins-1β and -8, and lactoferrin, are significantly increased and upregulate cyclooxygenase 2, which results in the synthesis of prostaglandin in the epithelial cells and production of substance P by the inflammatory cells. These processes decrease net sodium absorption and increase net chloride secretion, thereby causing the secretory diarrhea and clinical dehydration often seen with this infection.

Cryptosporidium oocysts have at least five characteristics that make this organism a common problem and that help define the potential risk for person-to-person spread and for waterborne and food-borne disease outbreaks. First, *Cryptosporidium* oocysts are resistant to many chemical disinfectants, such as chlorine. Second, the organism is highly infectious, with the median *C. parvum* infectious dose being 132 or fewer oocysts. Third, the size of the oocysts, 2 to 5 µm, allows them to pass through many conventional filters. Fourth, the monoxenous life cycle allows infectious oocysts to be excreted in large numbers in feces, from where they can easily spread. Fifth, the organism is associated with geographic, seasonal, and socioeconomic differences in its distribution.

CLINICAL MANIFESTATIONS

In immunocompetent hosts, cryptosporidiosis is a self-limited infection that affects all age groups and both sexes. In developing countries, the disease occurs most frequently in children younger than 5 years because of high rates of fecal-oral exposure and the development of partial immunity in older children and adults. In developed countries, the disease occurs at all ages, and most cases are associated with small waterborne outbreaks, frequently with contamination of recreational water.

After an incubation period of approximately 1 week (range of 1 to 30 days), diarrhea can be of sudden onset, frequently with voluminous watery stools, abdominal pain, nausea or vomiting, bloating, malaise, fatigue, dehydration, weight loss, and occasional fever. Rarely, respiratory infection and cough have been reported. In normal hosts, the disease usually persists for 1 to 3 weeks but sometimes persists for more than a month. Shedding of oocysts typically continues for 1 to 2 weeks but can occur for up to 2 months. Patients who have T-cell immune deficiency (e.g., patients with hematologic malignant neoplasms, primary T-cell deficiencies, solid organ transplants, and HIV/AIDS) are at high risk for more severe disease and death.

Immunocompetent Host

Most patients who are infected during outbreaks or travel are adults, who usually have watery diarrhea with a median duration of 14 days (range of 1 to 100 days), regardless of whether the infection is with *C. parvum* or *C. hominis*. Recurrence of diarrhea is common and occurs in about 30 to 40% of patients. Abdominal pain (about 85 to 95%), vomiting (about 50 to 65%), fever (about 55 to 60%), and bloody diarrhea (about 10%) are common accompanying symptoms. Patients may continue to shed oocysts for 7 months despite being asymptomatic.

Immunocompromised Hosts

Low $CD4^+$ lymphocyte counts in HIV-infected patients are associated with severe cryptosporidial diarrhea. For example, patients with $CD4^+$ counts higher than 180/µL usually have transient or self-limited disease, whereas patients with $CD4^+$ counts lower than 50/µL often have severe disease with more than 2 L of stool per day. Not surprisingly, the introduction of highly active antiretroviral therapy has greatly reduced rates of cryptosporidiosis in patients with HIV/AIDS (Chapter 357). In resource-limited settings, asymptomatic carriage of the parasite is common in individuals with HIV/AIDS.

Patients who have other immune disorders or hematologic malignant neoplasms are at higher risk for more severe, prolonged, or extensive disease, with infection occasionally extending to the gallbladder, the pancreatic duct, and even the bronchial tree. Complications can include pancreatitis, cholecystitis, sclerosing cholangitis, papillitis, and terminal bile duct stenosis, with subsequent biliary cirrhosis.

Cryptosporidium spp infection can also cause diarrhea in recipients of solid organ transplants, either as sporadic infection or infection associated with outbreaks related to exposure to recreational water.[13] Coinfection with other pathogens, extraintestinal involvement (biliary tract and lungs), and relapse also occur in these patients.

Childhood Cryptosporidiosis in Developing Countries

In developing countries, cryptosporidiosis is associated with prolonged (7 to 13 days) or persistent (≥14 days) diarrhea, increased overall burden of diarrhea, risk for malnutrition, stunted growth, impaired cognitive function, and mortality.[14] Immunocompetent hosts in endemic settings acquire immunity and are less susceptible to infection compared with travelers from nonendemic settings. Immunocompromised hosts are prone to symptomatic infections and prolonged asymptomatic shedding/carriage, regardless of their area of residence.

DIAGNOSIS

The clinical manifestations and physical examination findings in patients with cryptosporidiosis are not unique. The differential diagnosis should include other causes of infectious gastroenteritis, such as *Giardia* (Chapter 322), *Cyclospora* (Chapter 324), *Isospora* (Chapter 324), microsporidia (Chapter 324), *Escherichia coli* (Chapter 280), *Campylobacter* (Chapter 284), *Salmonella* (Chapter 279), *Shigella* (Chapter 285), rotavirus (Chapter 350), norovirus (Chapter 350), and others (Chapter 262).

Definitive diagnosis of *Cryptosporidium* enteric infection is made by stool examination. Commercially available enzyme-linked immunoassays have a sensitivity and specificity approaching 100% for *Cryptosporidium*.[15] Polymerase chain reaction testing can detect as few as 50 to 500 oocysts per milliliter of liquid stool and can be used to differentiate or even to quantify *Cryptosporidium* spp and genotypes.[16] Traditional microscopic methods, which require staining of oocysts, are less sensitive and now rarely used in developed countries.

TREATMENT

For severe disease, oral rehydration therapy or intravenous fluid replacement is key to preventing dehydration and risk for immediate death. In immunocompetent adults, nitazoxanide (500 mg twice daily for 3 days) can increase the rate of resolution of symptoms within 4 days, from about 30% to over 90%, and speed the clearing of oocysts.[A1]

In immunosuppressed patients, however, nitazoxanide has not been proven to be beneficial.[17] In patients with HIV/AIDS, highly active, antiretroviral therapy is the most important treatment to prevent and reduce the severity and frequency of cryptosporidiosis. In transplant recipients, prolonged courses of antiparasitic treatment (e.g., nitazoxanide 500 to 1000 mg twice daily for at least 2 weeks) and/or reduction of immunosuppression have been reported to yield anecdotal success.

PREVENTION

Prevention of person-to-person spread is dependent on personal hygiene, such as frequent handwashing after using or cleaning the toilet, changing diapers, and caring for a person with diarrhea.[18] Individuals who are infected with cryptosporidiosis should be excluded from the workplace setting until 48 hours after the last diarrheal episode. Handwashing facilities should be available and used at farms to facilitate personal hygiene.

Because most outbreaks of cryptosporidiosis are linked to oocysts in source water, routine surveys of treated water for this parasite are key for preventing major spread of this disease. Optimization of multibarrier approaches, including chemical treatment and water filtration, is highly recommended. Ultraviolet irradiation and ozone can effectively inactivate *Cryptosporidium* cysts in water and may prove useful in controlling the transmission of waterborne protozoa.

PROGNOSIS

In adults, cryptosporidiosis is usually a self-limited disease. Nevertheless, systemic (fatigue), gastrointestinal, and joint symptoms can persist for several months after the initial infection. In epidemics, the mortality rate may be as high as 3 per 10,000 in symptomatic people in the general population. For severely immunocompromised AIDS patients, cryptosporidiosis can be difficult to eradicate and is associated with a poor prognosis.

GIARDIASIS

DAVID R. HILL

DEFINITION

Giardia lamblia (*Giardia duodenalis, Giardia intestinalis*) is a ubiquitous, small intestinal protozoan parasite of humans and other mammals. It is the most common parasitic infection of the gastrointestinal tract in the United States as well as worldwide, and it is responsible for outbreaks of diarrhea and sporadic endemic disease.[1,2]

The Pathogen

Giardia has a simple life cycle. The trophozoite, which is 9 to 21 µm long, 5 to 15 µm wide, and 2 to 4 µm thick (Fig. 322-1), resides in the small intestine and is responsible for the manifestations of disease. It has four pairs of flagella, two nuclei, and a ventral sucking disc by which it may adhere to intestinal epithelial cells. The dorsal surface is pear shaped and bilaterally symmetrical, with the two highly characteristic nuclei best visualized after staining. In the lower small intestine, the trophozoite develops into an environmentally resistant cyst (Fig. 322-2). Detection of soluble cyst wall proteins in the feces forms the basis of many stool antigen assays.

Excreted cysts, which are mature and infectious, are oval and about 8 to 12 µm in length and 7 to 10 µm in width (see Fig. 322-2). After ingestion and exposure to acid and proteases in the stomach and intestines, they excyst in the small intestine, where each cyst forms two trophozoites, which quickly divide. In vitro, trophozoites double in number every 6 hours for the fastest growing isolates.

A number of morphologically identical but genetically distinct *Giardia* infect humans and animals and are divided into eight assemblages. Humans, as well as some animals, are typically infected with either assemblage A or B; other assemblages occasionally infect humans.[3,4] Assemblages A and B are genetically and biologically diverse and appear to be two separate species.[5]

Giardia is well adapted to its existence as a parasite. It has two equal functioning nuclei and lacks mitochondria and peroxisomes. It has a simplified metabolism and is dependent on the host for nutrients such as purines, pyrimidines, cysteine, phospholipids, cholesterol, and most amino acids except for alanine. The WB isolate, assemblage A, has a compact genome (11.7 Mb) with unusually short promoters. The parasite's rigid cytoskeleton is composed of unique families of structural proteins and carbohydrates.[6]

Giardia is the only bowel-dwelling parasite that undergoes antigenic variation. Only one of a family of about 250 variant-specific proteins (VSPs) is expressed on the surface of the trophozoite at a time. Both immune and biologic selection of trophozoites that express specific VSPs occurs in humans and animals with giardiasis. Expressed VSPs must be compatible with the host's intestinal environment; antibodies to VSPs are inhibitory or cytotoxic. Whereas all VSPs are transcribed, all but one of the transcripts are eliminated by RNA interference–based mechanisms, thereby resulting in expression of a single VSP surface protein. Exactly how selection and switching occur is unclear.

EPIDEMIOLOGY

Giardia is among the most common parasitic infections of humans. It is highly infectious, and cysts are frequently excreted in large numbers (as high as 10^7 cysts per gram of feces), especially in young children. Cysts can survive for months in cold water, are relatively resistant to chlorination, but are intolerant of desiccation and heat compared with the ova of cryptosporidia (Chapter 321) and helminths. Experimentally, between 10 and 100 cysts are sufficient to establish infection. Consequently, ingestion of water or food that contains low levels of contamination can result in infection.

The overall incidence rate is about 6 cases per 100,000 population in the United States, and approximately 20,000 cases are reported annually.[7] However actual infections may exceed 1 million per year because of underreporting.

Infections are most common in young children and are more frequent in summer and fall months, possibly due to increased travel and exposure to environmental water during the warmer months. In low-income, highly endemic regions, almost all children are infected by 2 to 3 years of age, about 20% of them persistently. In these settings simultaneous infection with other enteric pathogens is common.

Giardiasis is acquired after ingestion of contaminated water or food or through person-to-person contact. Before the advent of modern water treatment methods, large outbreaks in high-income countries such as the United States occurred after ingestion of contaminated drinking water obtained from surface sources such as reservoirs, lakes, and mountain streams. Now, however, ingestion of contaminated recreational water from pools or lakes is a more common source of outbreaks.[8] Outbreaks from contaminated food or infected food handlers are well described. Currently, only 1 to 2% of giardiasis cases are associated with identified outbreaks. Backpackers who ingest untreated surface water are at risk.

Worldwide, person-to-person transmission is the most common source of infection, especially in daycare centers, among family members with infected children, and following sexual practices that lead to fecal-oral contact.[9] Although partial immunity can develop in previously exposed adults, reinfection after treatment in children is common in highly endemic areas. Longer-term travel, particularly to South Asia, increases the risk of giardiasis. For the returned traveler (Chapter 265) with intermittent or persistent diarrhea, giardiasis should be excluded. *Giardia* infections tend to be severe in patients who have common variable immunodeficiency but are not more common in persons with selective immunoglobulin (Ig) A deficiency.

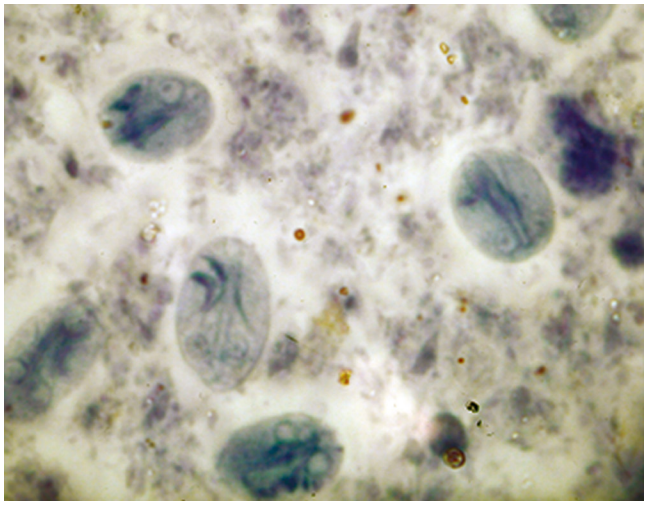

FIGURE 322-2. Iron hematoxylin stain of *Giardia lamblia* cysts from stool.

ABSTRACT

Giardia lamblia is a global enteric parasite that affects upward of 300 million people annually. *Giardia* is highly infectious; its cysts, which can survive for months in cold water, are excreted in large numbers in feces, especially in young children. The parasite is acquired after ingestion of contaminated water or food or through person-to-person contact, with the latter being the most frequent mode of infection among children and their families. Clinical manifestations, course, and duration of infection are variable. Acute disease manifests with diarrhea, nausea, anorexia, gas, distention, and abdominal cramping, but patients generally are not as sick as those with bacterial diarrhea. Acute symptoms can resolve, wax and wane, or transition into a chronic phase. Constant reinfection is common in children in highly endemic regions. Diagnosis is made by detection of cysts, trophozoites, parasitic antigens, or DNA in fecal samples. Nitroimidazole drugs, such as tinidazole, are the treatment of choice.

PATHOBIOLOGY

Giardia infections involve complex interactions between host and parasite. The two assemblages (A and B) that typically infect humans are composed of genetically distinguishable isolates, which may vary in infectivity, antigenicity, and virulence.[10] In addition, human hosts vary in susceptibility to infection and disease and in the response or tolerance to infection. Multiple pathogenic mechanisms likely explain the varied clinical manifestations as well as the contrasting situation in which high rates of infection and disease are seen in water-borne outbreaks of giardiasis in regions where infections are sporadic, as in the United States, compared with the mostly asymptomatic infections in children in highly endemic low-income regions. In addition, infection with *Giardia* can lead to malabsorption, weight loss, and nutritional deficiencies in some settings and little effect on nutritional parameters in other settings.[11]

Giardia is strictly an intraluminal parasite that likely adheres to the epithelium by way of an adhesive or sucking disc. Invasion of the epithelium either does not occur or is rare. Large numbers of parasites can cover the intestinal epithelial surface, thereby potentially interfering with brush border disaccharidase activity. *Giardia* produce cysteine proteases, including cathepsin B–like proteases, that experimentally can disrupt epithelial cell tight junctions, lead to epithelial cell apoptosis, break down intestinal mucus, and degrade host immune factors. There is no evidence of production of a classic secretory enterotoxin. Of patients with persistent giardiasis after treatment, nearly half exhibit inflammation on small bowel biopsy specimens, thereby supporting the view that chronic inflammatory responses contribute to disease at least in this subset.

The intestinal microbiome, the nutritional status of the host, and available nutrients also can affect pathogenesis.[12,13] Experimentally, high glucose can counteract caspase-3–dependent apoptosis, and parasite arginine consumption may increase gut colonization. Sequential coinfection of mice with *Giardia* and then enteroaggregative *Escherichia coli* can increase weight loss. Alteration of the intestinal microbiome in giardiasis may contribute to both susceptibility and resistance to infection, perhaps explaining some of the clinical differences of *Giardia* infection between children in highly endemic as compared with low-incidence regions.

In experimental human challenges, in which the infecting parasite was well characterized and the inoculum known, rechallenge with the same isolate after treatment results in brief, asymptomatic infection, thereby suggesting partial immunity. Based on animal studies, intestinal antibodies (IgA), T-cells (particularly $CD4^+$ helper T-cells), and interleukin-17 appear to be important for the immune response to infection.

CLINICAL MANIFESTATIONS

The clinical manifestations, course, and duration of *Giardia* infections are variable. Infections may be self-limited or persistent, asymptomatic or symptomatic.[14] About 50% of newly infected individuals may develop symptoms.

In a well-documented foodborne outbreak of giardiasis, the incubation period was 2 to 19 days, with peak symptoms at 5 to 6 days. Symptoms in this outbreak continued for a median of 18 days.

Acute disease manifestations are characterized by diarrhea, nausea, anorexia, dehydration, flatulence, eructation, foul-smelling stools, distention, abdominal cramping, and weight loss. Malabsorption is more commonly seen in chronic infection. Fever and vomiting are uncommon. Blood, mucus, and polymorphonuclear cells in the stool, which are not usual features of small bowel infections, should suggest an alternative or additional diagnosis. Patients generally are not as sick as patients who have bacterial diarrheas, but dehydration, although uncommon, may be severe and require hospitalization. On occasion, nausea and vomiting will predominate and suggest other causes.

Acute symptoms can resolve, wax and wane, or settle into a chronic phase, which can be prolonged and persist for weeks to months. These long-lasting symptoms should prompt a search for *Giardia*. Lactose deficiency (Chapter 126), which is common and can persist for weeks after treatment, must be distinguished from relapse or reinfection. In extreme cases, malabsorption and weight loss are severe and mimic celiac disease (Chapter 126).

A typical clinical scenario is a mildly to moderately ill person who complains of an increased number of urgent loose stools, with flatus, cramping, anorexia, and weight loss. There may be periods when the person feels better only to relapse and become noticeably worse. After days to several weeks, the individual will seek medical help. Similar to other causes of infectious diarrheas, symptoms can continue after successful treatment. Some patients will develop persistent irritable bowel syndrome (Chapter 123) and/or chronic fatigue syndrome (Chapter 253).[15] Uncommonly, *Giardia* is found in biliary and pancreatic ducts and can cause cholecystitis and pancreatitis. Extraintestinal manifestations including rash, reactive arthritis,[16] eye complaints, and cognitive deficiencies, are uncommon.

In highly endemic regions *Giardia* is an uncommon cause of acute, moderately severe, or severe diarrhea compared with agents such as rotavirus (Chapter 350), enterotoxigenic *E. coli* (Chapter 280), *Shigella* (Chapter 285), *Campylobacter* (Chapter 279), and *Cryptosporidium* (Chapter 321). Nevertheless, endemic *Giardia* can be associated with long-lasting diarrhea (≥14 days), and chronic infection can lead to malnutrition and stunting. In settings of repeated infection, it is possible that *Giardia* protects against other enteric pathogens.

DIAGNOSIS

Many patients who seek care for gastrointestinal symptoms consistent with giardiasis are not diagnosed until they have had multiple visits. The clinician should consider the diagnosis by putting risk factors and symptoms together, and test for *Giardia*.

The diagnosis of giardiasis is based on detection of parasite antigens, DNA, cysts, or trophozoites in fecal samples. Stool antigen tests are more sensitive than microscopy and do not require a trained microscopist. Molecular detection methods, often as part of an array of other enteric pathogens, are the most sensitive approach.[17] Because excretion of cysts may be variable or in low concentrations, a single-stool microscopy for ova and parasites is only 50 to 80% sensitive, so three stool examinations may be necessary. Cysts appear in the stool 6 to 15 days (mean, 9 days) after infection; *Giardia* antigen may be detected before cysts are excreted.

Examination of small intestinal biopsy samples or intestinal contents for trophozoites is rarely needed to establish or to confirm the diagnosis because of the high sensitivity and specificity of stool antigen or molecular assays. Biopsy may be performed, however, when looking for other causes of an enteric syndrome.

Other laboratory findings are nonspecific. The white blood cell count and liver enzymes are usually normal. Electrolyte disturbances can be present if diarrhea and vomiting are severe. White blood cells, lactoferrin, blood, and mucus are not found in the stool. Immunoglobulin levels will be abnormally low or absent in susceptible hypogammaglobulinemic individuals.

TREATMENT

A single dose of tinidazole (Tindamax), which is a nitroimidazole drug similar to metronidazole (Flagyl), is the treatment of choice for giardiasis.[A1] In adults, the dose is 2 g orally; in children, the dose is 50 mg/kg up to a maximum of 2 g. Other nitroimidazoles (e.g., ornidazole and secnidazole) that are not approved in the United States are also effective. Metronidazole, which is less efficacious and has more side effects, has been used to treat giardiasis for decades but has never been approved by the U.S. Food and Drug Administration (FDA) for this indication; it requires multiple dosing at 250 mg orally three times a day for 5 to 7 days for adults and 15 mg/kg/day in three divided doses for 5 to 7 days for children. Alcohol should not be taken concomitantly with any of the nitroimidazoles because of the possibility of a disulfiram-like reaction with these drugs.

Albendazole (400 mg/day for 5 days), not presently approved by the FDA for treatment of giardiasis, may be an acceptable alternative to the nitroimidazoles, with fewer side effects. However, experience with this drug is limited.

Nitazoxanide has broad activity against protozoa, helminths, and bacteria and is FDA-approved for the treatment of giardiasis with an efficacy of 65 to 85%.[A2] It is given at a dose of 100 mg orally every 12 hours for 3 days for children ages 12 months to 3 years, 200 mg orally every 12 hours for 3 days for children 4 to 11 years of age, and 500 mg orally every 12 hours for 3 days for persons older than 12 years. Because it is available in a liquid suspension as well as in a 500-mg tablet, it may be easier to give to young children. It should be given with food. Most of the side effects are gastrointestinal symptoms and headache.

Paromomycin, a nonabsorbable aminoglycoside, has been used in pregnant women to avoid the theoretical fetal adverse events of nitroimidazoles, particularly during the first trimester. It is given to adults at a dose of 500 mg three times a day for 5 to 10 days and to children at 25 to 35 mg/kg/day orally in three divided doses for 5 to 10 days. Quinacrine (100 mg orally three times per day for 5 days)[18] and furazolidone (100 mg orally four times per day for 7 to 10 days under expert supervision) are also active against *Giardia* but should generally be reserved for use in particular situations, such as nitroimidazole resistance.[19]

Patients who do not respond to treatment frequently have a return of symptoms days to weeks after cessation of therapy and require either re-treatment with an alternative class of drug or combination therapy. Nitroimidazole-resistant infections are increasingly common, particularly in returned travelers from South Asia. These patients usually respond to combination treatment (e.g., metronidazole plus albendazole; metronidazole plus quinacrine) or quinacrine monotherapy.[20]

PREVENTION

Infection is prevented by personal hygiene, proper disposal of sewage, removal or killing of cysts from water supplies, and preventing contamination of food and water. Cysts are susceptible to heating and filtration with small-volume water filters of 0.2 to 1 μm. Heating water (bringing it to a boil) inactivates *Giardia* as well as other common enteric pathogens. Cysts are not reliably susceptible to chlorination because the concentrations of chlorine, and water temperatures, turbidity, and pH present when treating commercial water supplies are suboptimal. Four drops of 5.25% bleach to 1 L for 1 hour at room temperature is sufficient for killing. At lower temperatures, inactivation may not be complete.

PROGNOSIS

Most persons who are diagnosed and treated will recover without long-term consequences, but a subset develop long-term irritable bowel syndrome. Patients who have common variable immunodeficiency (Chapter 231) have more severe disease that is difficult to treat. Even though most human immunodeficiency virus–infected patients respond to usual treatment, a subset develop recurrent or repeated infections that are difficult to treat.

323 AMEBIASIS

WILLIAM A. PETRI, JR.

DEFINITION

Amebiasis is due to infection with the enteric protozoan parasite *Entamoeba histolytica*. Amebiasis can cause asymptomatic colonization, diarrhea, dysentery, and colitis. It also can spread extraintestinally to cause liver and rarely brain abscess (Fig. 323-1).

The Pathogen

E. histolytica has a low infectious dose (<100 organisms), is resistant to chlorine, and is environmentally stable. Certain genotypes of *E. histolytica* appear to be associated with the propensity for colonization, whereas others are associated with invasion. Its tissue-destructive properties are the reason for the parasite's being named *histolytica*.

EPIDEMIOLOGY

Most *E. histolytica* infections occur in the developing world, including the Indian subcontinent, Southeast Asia, sub-Saharan Africa, and Central and South America, as a result of fecal-oral transmission. A national serologic survey in Mexico demonstrated antibody to *E. histolytica* in 8.4% of the population. In an urban slum of Fortaleza, Brazil, 25% of the population carried antibody to *E. histolytica*, and the prevalence in children 6 to 14 years of age was 40%. In Dhaka, Bangladesh, where diarrheal diseases are the leading cause of childhood death, the annual incidences of amebic infection, diarrhea, and dysentery are about 45%, 9%, and 3%, respectively. The annual incidences of amebic liver abscess was 21 cases per 100,000 inhabitants in Hue City, Vietnam. The best current estimate by the World Health Organization is that *E. histolytica* infection results in nearly 50 million symptomatic cases each year worldwide and as many as 100,000 deaths annually.

In the United States, amebiasis is the third most common parasitic infection after giardiasis and cryptosporidiosis (1.2 cases/100,000 U.S. population). Most cases in industrialized countries occur in travelers to and immigrants from endemic regions as well as in institutionalized individuals. In returning travelers (Chapter 265), diarrhea is the predominant reason for a patient to visit a physician, and amebiasis is the second most common cause of diarrhea in returning travelers. Previously reported high rates of *E. histolytica* infection in men who have sex with men in the United States[1] actually reflect a high prevalence of *Entamoeba dispar* infection in this population. In contrast, in Asia, amebiasis is more frequently an initial symptom of human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome because of the common risk for acquisition of both HIV infection and amebiasis through the sexual practices of men who have sex with men. The typical patient with an amebic liver abscess in the United States is a 20- to 40-year-old Hispanic male immigrant. Several groups are at increased risk for severe amebiasis, including the very young or old, malnourished persons, pregnant women, and patients treated with corticosteroids.

PATHOBIOLOGY

Killing of host cells[2] is required for invasion of the intestine by the parasite. The process of host cell destruction includes sequential steps of adherence, a nibbling-like process termed *amebic trogocytosis*, contact-dependent cytotoxicity, and finally phagocytosis of the host cell corpse. The initial contact of parasite to host is mediated by the parasite's galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc)–specific lectin, which binds to carbohydrate determinants on the host's intestinal epithelium.[3] Human cells die by apoptosis induced by *E. histolytica*, a process that requires attachment of the Gal/GalNAc lectin to a host cell's receptor, as well as the parasite's acid intracellular vesicles, which may serve as delivery vehicles for an amebic pore-forming protein.[4] *E. histolytica* initiates apoptosis in host cells by directly activating the host cell's distal apoptotic machinery; caspase 3 is activated within minutes of *E. histolytica* adherence, a caspase 3 inhibitor blocks *E. histolytica* killing, and caspase 3–deficient or bcl-2–overexpressing mice are resistant to amebic infection. Recognition and ingestion of the apoptotic host cell's corpse are required for colonic infection by the parasite, and multiple ligands and receptors are involved, including the Gal/GalNAc lectin, a phosphatidylserine receptor, serine-rich *E. histolytica* protein, and collectins. After ingestion of the corpse of the host cell, additional parasitic factors participate in invasion into the intestinal mucosa. For example, *E. histolytica* encodes at least 44 cysteine proteinase genes that have been implicated in degradation of colonic mucin glycoproteins; digestion of extracellular matrix, hemoglobin, and villin; and inactivation of interleukin-18 (IL-18).

The innate immune response to amebic infection is coordinated by lymphoid cells type 2, which produce a protective type 2 immune response in response to amebic infection. In the murine model of intestinal amebiasis, innate resistance is conferred by nonhematopoietic cells, thus suggesting the importance of epithelial production of cytokines such as tumor necrosis factor-α (TNF-α), IL-1α, IL-6, IL-8, growth-related oncogene-α (GRO-α), and granulocyte-macrophage colony-stimulating factor. Granulocytes are the earliest innate cellular immune response (within 1 to 2 days) for both intestinal and hepatic amebiasis. Depletion of neutrophils or eosinophils in a murine model results in exacerbated amebic hepatic and intestinal disease. Macrophages and T lymphocytes are also recruited by day 3 of an infection. Macrophages acquire amebicidal activity after in vitro stimulation with interferon-γ (IFN-γ), TNF-α, or colony-stimulating factor 1.

The acquired immune response reflects the opposing roles of IL-4 and IFN-γ in persistence and clearance of amebic infection, respectively. Inbred mice of the CBA strain are susceptible to intestinal amebiasis and develop a rapid T_H2 phenotypic immune response, and this response is deleterious insofar as inhibition of IL-4 can convert the response to a healing IFN-γ response. The IL-33-ILC2 pathway also appears to be an important host defense mechanism.[5] Effective acquired immunity in humans is associated with both a systemic IFN-γ and a mucosal immunoglobulin (Ig)A response directed at the Gal/GalNAc lectin. Children with mucosal IgA against the Gal/GalNAc lectin have 86% fewer new *E. histolytica* infections in the following year. Similarly, the risk for amebiasis is 50% lower in children who are in the 50th percentile and above for the production of IFN-γ by peripheral blood mononuclear cells stimulated with soluble amebic antigen. Children with an amino acid polymorphism in the receptor for leptin are protected from symptomatic infection with amebiasis, thereby reflecting the importance of leptin for gut mucosal innate immunity.

PREVENTION

Infection is prevented by personal hygiene, proper disposal of sewage, removal or killing of cysts from water supplies, and preventing contamination of food and water. Cysts are susceptible to heating and filtration with small-volume water filters of 0.2 to 1 μm. Heating water (bringing it to a boil) inactivates *Giardia* as well as other common enteric pathogens. Cysts are not reliably susceptible to chlorination because the concentrations of chlorine, and water temperatures, turbidity, and pH present when treating commercial water supplies are suboptimal. Four drops of 5.25% bleach to 1 L for 1 hour at room temperature is sufficient for killing. At lower temperatures, inactivation may not be complete.

PROGNOSIS

Most persons who are diagnosed and treated will recover without long-term consequences, but a subset develop long-term irritable bowel syndrome. Patients who have common variable immunodeficiency (Chapter 231) have more severe disease that is difficult to treat. Even though most human immunodeficiency virus–infected patients respond to usual treatment, a subset develop recurrent or repeated infections that are difficult to treat.

323 AMEBIASIS

WILLIAM A. PETRI, JR.

DEFINITION

Amebiasis is due to infection with the enteric protozoan parasite *Entamoeba histolytica*. Amebiasis can cause asymptomatic colonization, diarrhea, dysentery, and colitis. It also can spread extraintestinally to cause liver and rarely brain abscess (Fig. 323-1).

The Pathogen

E. histolytica has a low infectious dose (<100 organisms), is resistant to chlorine, and is environmentally stable. Certain genotypes of *E. histolytica* appear to be associated with the propensity for colonization, whereas others are associated with invasion. Its tissue-destructive properties are the reason for the parasite's being named *histolytica*.

EPIDEMIOLOGY

Most *E. histolytica* infections occur in the developing world, including the Indian subcontinent, Southeast Asia, sub-Saharan Africa, and Central and South America, as a result of fecal-oral transmission. A national serologic survey in Mexico demonstrated antibody to *E. histolytica* in 8.4% of the population. In an urban slum of Fortaleza, Brazil, 25% of the population carried antibody to *E. histolytica*, and the prevalence in children 6 to 14 years of age was 40%. In Dhaka, Bangladesh, where diarrheal diseases are the leading cause of childhood death, the annual incidences of amebic infection, diarrhea, and dysentery are about 45%, 9%, and 3%, respectively. The annual incidences of amebic liver abscess was 21 cases per 100,000 inhabitants in Hue City, Vietnam. The best current estimate by the World Health Organization is that *E. histolytica* infection results in nearly 50 million symptomatic cases each year worldwide and as many as 100,000 deaths annually.

In the United States, amebiasis is the third most common parasitic infection after giardiasis and cryptosporidiosis (1.2 cases/100,000 U.S. population). Most cases in industrialized countries occur in travelers to and immigrants from endemic regions as well as in institutionalized individuals. In returning travelers (Chapter 265), diarrhea is the predominant reason for a patient to visit a physician, and amebiasis is the second most common cause of diarrhea in returning travelers. Previously reported high rates of *E. histolytica* infection in men who have sex with men in the United States[1] actually reflect a high prevalence of *Entamoeba dispar* infection in this population. In contrast, in Asia, amebiasis is more frequently an initial symptom of human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome because of the common risk for acquisition of both HIV infection and amebiasis through the sexual practices of men who have sex with men. The typical patient with an amebic liver abscess in the United States is a 20- to 40-year-old Hispanic male immigrant. Several groups are at increased risk for severe amebiasis, including the very young or old, malnourished persons, pregnant women, and patients treated with corticosteroids.

PATHOBIOLOGY

Killing of host cells[2] is required for invasion of the intestine by the parasite. The process of host cell destruction includes sequential steps of adherence, a nibbling-like process termed *amebic trogocytosis*, contact-dependent cytotoxicity, and finally phagocytosis of the host cell corpse. The initial contact of parasite to host is mediated by the parasite's galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc)–specific lectin, which binds to carbohydrate determinants on the host's intestinal epithelium.[3] Human cells die by apoptosis induced by *E. histolytica*, a process that requires attachment of the Gal/GalNAc lectin to a host cell's receptor, as well as the parasite's acid intracellular vesicles, which may serve as delivery vehicles for an amebic pore-forming protein.[4] *E. histolytica* initiates apoptosis in host cells by directly activating the host cell's distal apoptotic machinery; caspase 3 is activated within minutes of *E. histolytica* adherence, a caspase 3 inhibitor blocks *E. histolytica* killing, and caspase 3–deficient or bcl-2–overexpressing mice are resistant to amebic infection. Recognition and ingestion of the apoptotic host cell's corpse are required for colonic infection by the parasite, and multiple ligands and receptors are involved, including the Gal/GalNAc lectin, a phosphatidylserine receptor, serine-rich *E. histolytica* protein, and collectins. After ingestion of the corpse of the host cell, additional parasitic factors participate in invasion into the intestinal mucosa. For example, *E. histolytica* encodes at least 44 cysteine proteinase genes that have been implicated in degradation of colonic mucin glycoproteins; digestion of extracellular matrix, hemoglobin, and villin; and inactivation of interleukin-18 (IL-18).

The innate immune response to amebic infection is coordinated by lymphoid cells type 2, which produce a protective type 2 immune response in response to amebic infection. In the murine model of intestinal amebiasis, innate resistance is conferred by nonhematopoietic cells, thus suggesting the importance of epithelial production of cytokines such as tumor necrosis factor-α (TNF-α), IL-1α, IL-6, IL-8, growth-related oncogene-α (GRO-α), and granulocyte-macrophage colony-stimulating factor. Granulocytes are the earliest innate cellular immune response (within 1 to 2 days) for both intestinal and hepatic amebiasis. Depletion of neutrophils or eosinophils in a murine model results in exacerbated amebic hepatic and intestinal disease. Macrophages and T lymphocytes are also recruited by day 3 of an infection. Macrophages acquire amebicidal activity after in vitro stimulation with interferon-γ (IFN-γ), TNF-α, or colony-stimulating factor 1.

The acquired immune response reflects the opposing roles of IL-4 and IFN-γ in persistence and clearance of amebic infection, respectively. Inbred mice of the CBA strain are susceptible to intestinal amebiasis and develop a rapid T_H2 phenotypic immune response, and this response is deleterious insofar as inhibition of IL-4 can convert the response to a healing IFN-γ response. The IL-33-ILC2 pathway also appears to be an important host defense mechanism.[5] Effective acquired immunity in humans is associated with both a systemic IFN-γ and a mucosal immunoglobulin (Ig)A response directed at the Gal/GalNAc lectin. Children with mucosal IgA against the Gal/GalNAc lectin have 86% fewer new *E. histolytica* infections in the following year. Similarly, the risk for amebiasis is 50% lower in children who are in the 50th percentile and above for the production of IFN-γ by peripheral blood mononuclear cells stimulated with soluble amebic antigen. Children with an amino acid polymorphism in the receptor for leptin are protected from symptomatic infection with amebiasis, thereby reflecting the importance of leptin for gut mucosal innate immunity.

ABSTRACT

The parasitic ameba *Entamoeba histolytica* is the cause of amebic colitis and liver abscess. Infection is mostly limited to low- and middle-income countries where poor sanitation facilitates fecal-oral spread. Diagnosis is by a combination of detecting parasitic DNA or antigen in feces and a positive blood serology. The mainstay of treatment is metronidazole. Free-living amebae including *Acanthamoeba, Balamuthia,* and *Naegleria* are causes of central nervous system infection, and *Acanthamoeba* also causes keratitis. Diagnosis is by PCR detection of amebic DNA, and treatment requires combination antimicrobials.

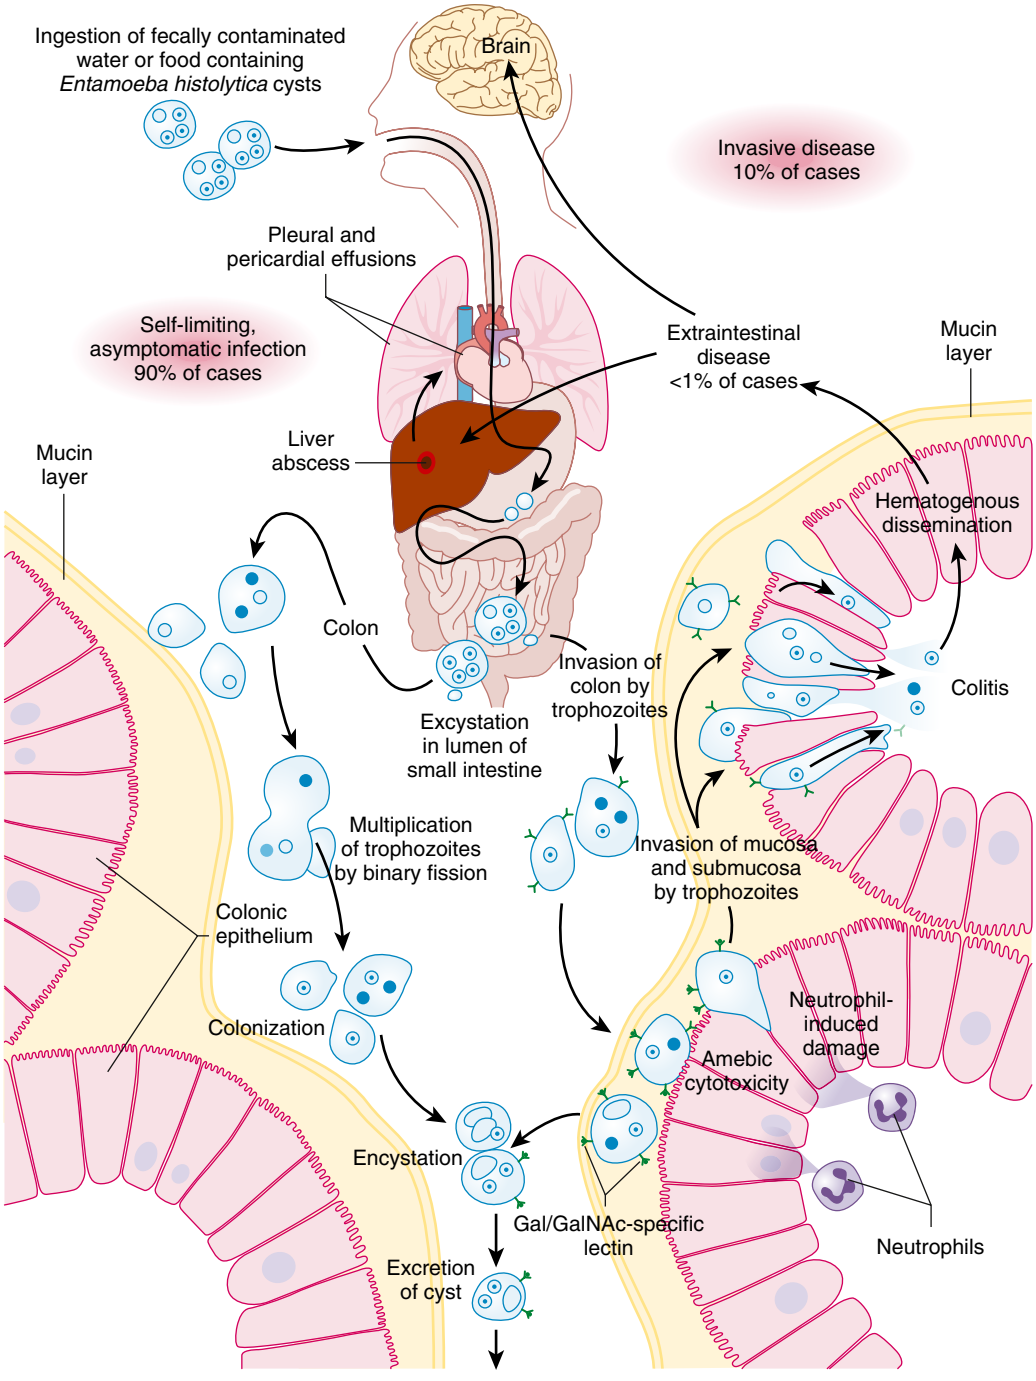

FIGURE 323-1. Life cycle of *Entamoeba histolytica*. Infection is normally initiated by the ingestion of fecally contaminated water or food containing *E. histolytica* cysts. The infective cyst form of the parasite survives passage through the stomach and small intestine. Excystation occurs in the bowel lumen, where motile and potentially invasive trophozoites are formed. In most infections, the trophozoites aggregate in the intestinal mucin layer and form new cysts, which results in a self-limited and asymptomatic infection. In some cases, however, adherence to and lysis of the colonic epithelium, mediated by the galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc)–specific lectin, initiates invasion of the colon by trophozoites. Neutrophils responding to the invasion contribute to cellular protection at the site of invasion. Once the intestinal epithelium is invaded, extraintestinal spread to the peritoneum, liver, and other sites may follow. Factors controlling invasion, as opposed to encystation, probably include parasitic "quorum sensing" signaled by the Gal/GalNAc-specific lectin, interactions of amebae with the bacterial flora of the intestine, and innate and acquired immune responses of the host. (Redrawn with permission from Haque R, Huston CD, Hughes M, et al. Current concepts: amebiasis. *N Engl J Med*. 2003;348:1565-1573.)

The composition of the gut microbiome also is associated with symptomatic amebiasis, likely by induction of an inflammatory immune response.

CLINICAL MANIFESTATIONS

Asymptomatic Intraluminal Amebiasis

The asymptomatic cyst-passing carrier state is the most common type of amebic infection. All *Entamoeba moshkovskii* and *E. dispar* infections and as many as 80% of *E. histolytica* infections are asymptomatic.[6] Asymptomatically infected individuals represent a risk to the community because they are a source of new infections and a risk to themselves because 1 in 10 to 20 colonized individuals progress to symptomatic infection.

Amebic Diarrhea

Amebic diarrhea without dysentery, which is defined as diarrhea in an *E. histolytica*–infected individual, is the most common amebic disease.[7] The mean duration of amebic diarrhea is about 3 days, and approximately 2% of cases of diarrhea are severe enough to warrant hospital evaluation in developing countries.

Amebic Dysentery or Colitis

Diarrhea with mucus or visible or microscopic blood in a patient with *E. histolytica* infection is the definition of amebic dysentery or colitis.[8] Approximately 15 to 33% of patients with *E. histolytica* diarrhea also have amebic dysentery. The onset of symptoms is typically gradual during a period of 3 or 4 weeks after infection, with abdominal tenderness and increasingly severe diarrhea being the primary

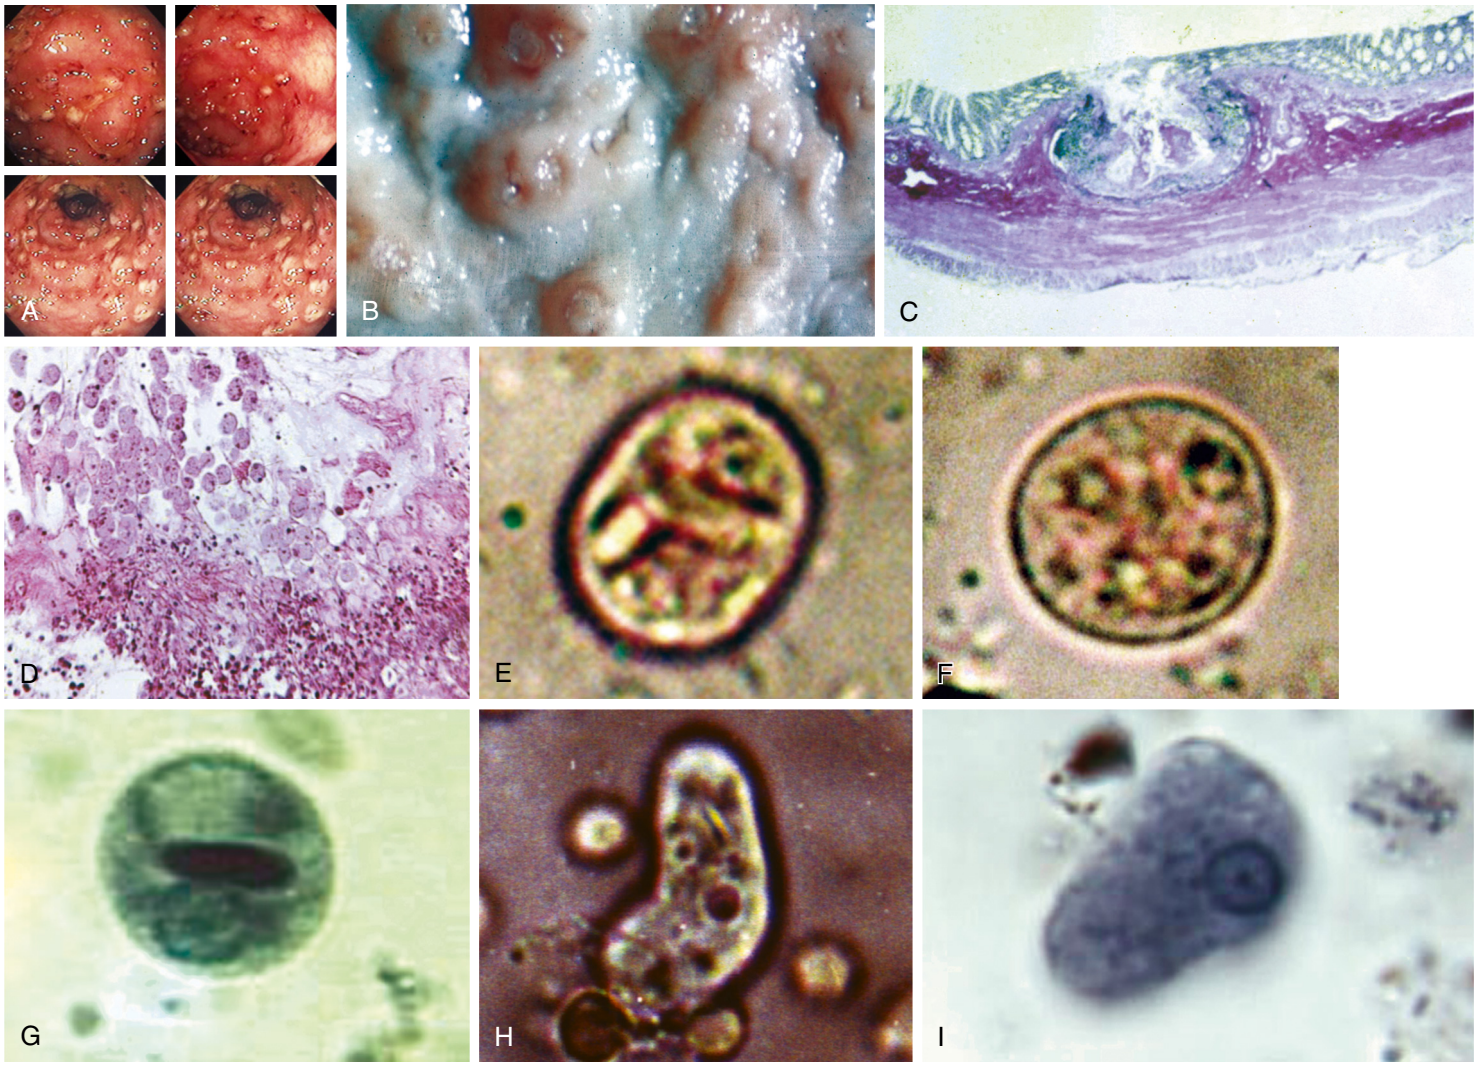

FIGURE 323-2. Endoscopic and pathologic features of intestinal amebiasis. (*B–D*, From the slide collection of the late Dr. Harrison Juniper.) (From Haque R, Huston CD, Hughes M, et al. Current concepts: amebiasis. *N Engl J Med*. 2003;348:1565-1573.)

complaints. By comparison, patients with bacterial causes of dysentery usually have only 1 or 2 days of symptoms (Chapter 262). Surprisingly, fever is present in only a minority of patients with amebic colitis. In young children, intussusception, perforation, peritonitis, or necrotizing colitis may develop rapidly (Fig. 323-2). Unusual manifestations of amebic colitis include toxic megacolon (0.5% of cases, usually requiring surgical intervention) and ameboma (granulation tissue in the colonic lumen mimicking colon cancer in appearance).

Amebic Liver Abscess

Amebic liver abscess (Chapter 137) is 10 times as common in men as in women and is unusual in children. The typical patient with an amebic liver abscess in the United States is a male immigrant from an endemic area, ages 20 to 40 years, with fever, right upper quadrant pain, leukocytosis, abnormal liver aminotransferase and alkaline phosphatase levels, and a defect seen on hepatic imaging studies.[9] Among travelers, the average interval between exposure and clinical presentation can be up to 18 months.[10] Most patients have 2 to 4 weeks of prior fever, cough, and abdominal pain in the right upper quadrant or epigastrium. Involvement of the diaphragmatic surface of the liver may lead to right-sided pleural pain or referred shoulder pain and an elevated right hemidiaphragm seen on chest radiography (Fig. 323-3). Hepatomegaly with point tenderness over the liver, below the ribs, or in the intercostal spaces is a typical finding.

Other Extraintestinal Infections

Thoracic amebiasis, which is the most common type of extra-abdominal amebiasis, occurs in about 10% of patients with amebic liver abscess. It develops by direct extension into the pleural cavity from the liver. Pericardial amebiasis, which is the next most common form, may result from rupture of a liver abscess in the left lobe of the liver into the pericardium or from extension of right-sided pleural amebiasis. Cerebral amebic abscesses have been found in about 0.5 to 5% of patients with amebic liver abscess. Other foci of infection are rare, but amebic rectovesical fistula formation and involvement of the pharynx, heart, aorta, and scapula have been reported. Cutaneous infection may arise from trophozoites emerging from the rectum.

DIAGNOSIS

Diagnosis of amebiasis is best accomplished by the combination of polymerase chain reaction (PCR) testing or antigen detection of the parasite in feces or at extraintestinal sites of invasion (e.g., pus obtained by fine needle aspiration of a liver abscess), often combined with serology.[11] The most sensitive diagnostic approach is the combined use of *E. histolytica*–specific antigen detection or PCR plus serology (Table 323-1). The detection of salivary IgA has a sensitivity and specificity of about 90%.[12] Examination of stool for ova and parasites should not be used to diagnose amebiasis. Amebic colitis also can be diagnosed by colonoscopy, which can show characteristic discrete ulcers or erosions with white or yellow exudates, especially in the cecum, and can identify trophozoites in about 90% of patients.

When a space-filling defect in the liver is observed, the differential diagnosis includes (1) amebiasis (most common in men with a history of travel to or residence in a developing country), (2) pyogenic or bacterial abscess (particularly

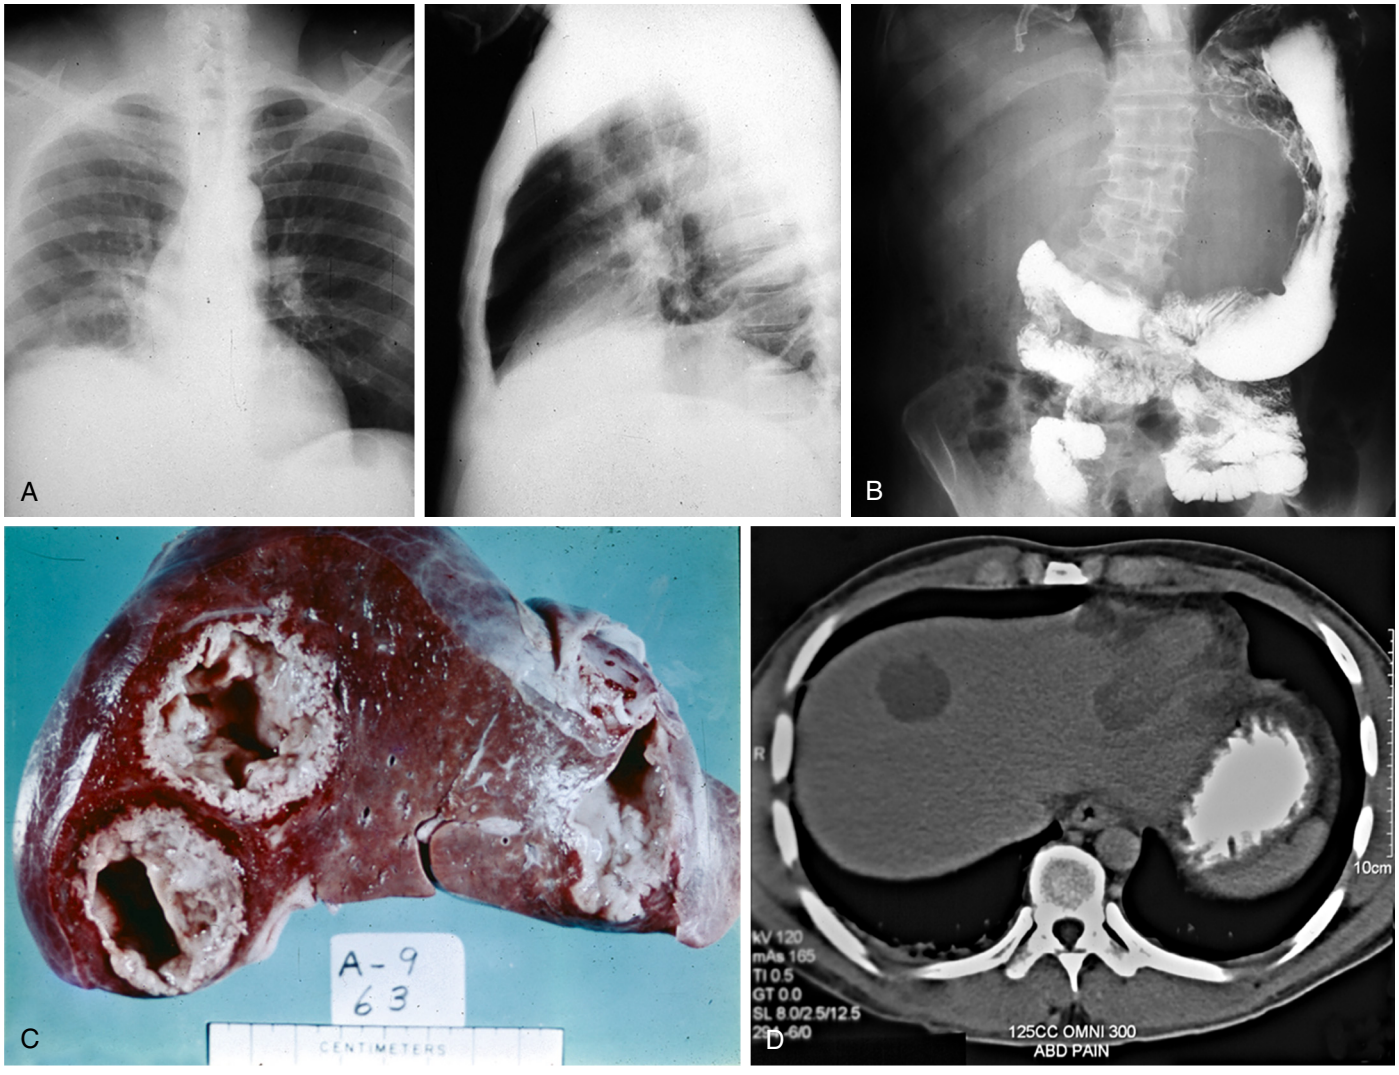

FIGURE 323-3. **Radiographic and pathologic features of extraintestinal amebiasis. A,** Left posteroanterior and right lateral chest radiographs in a patient with amebic liver abscess. The findings include an elevated right hemidiaphragm and evidence of atelectasis. **B,** Luminal narrowing revealed by barium enema examination in a patient with an ameboma. **C,** Two abscesses in the right lobe and one abscess in the left lobe of a patient with amebic liver abscess. **D,** Abdominal computed tomography showing one abscess in the right lobe and one abscess in the left lobe in a patient with amebic liver abscess. (From Haque R, Huston CD, Hughes M, et al. Current concepts: amebiasis. *N Engl J Med*. 2003;348:1565-1573.)

TABLE 323-1 SENSITIVITY OF TESTS FOR DIAGNOSIS OF AMEBIASIS

TEST	COLITIS	LIVER ABSCESS
Real-time PCR	>95%	>95%
Stool antigen detection	80%	≈40%
Microscopy: stool	25-60%	10-40%
Serum antigen detection	65%	>95%
Serologic testing (indirect hemagglutination)		
Acute	70%	70-80%
Convalescent	>90%	>90%
Microscopy: abscess fluid	N/A	≤20%

N/A = not available; PCR = polymerase chain reaction.
Modified from Haque R, Huston CD, Hughes M, et al. Current concepts: amebiasis. *N Engl J Med*. 2003;348:1565-1573.

suspected in women, patients with cholecystitis, the elderly, individuals with diabetes, and patients with jaundice; Chapter 137), (3) echinococcal abscess (which would be an incidental finding because echinococcal abscess should not cause pain or fever; Chapter 325), and (4) cancer. Most patients with amebic liver abscess will have detectable circulating antigen in serum as well as serum antiamebic antibodies.[13]

TREATMENT (ALSO SEE CHAPTER 315)

Noninvasive infection may be treated with paromomycin (Table 323-2), but invasive infections require treatment with nitroimidazoles, particularly tinidazole,[A1] metronidazole, secnidazole (2-g single dose), or ornidazole (500 mg 3 times daily for 5 days). For amebic colitis and liver abscess,[A2] tinidazole reduces treatment failure rates and adverse effects compared with metronidazole. Nitazoxanide (500 mg orally twice daily for 10 days) also appears to be superior to metronidazole for uncomplicated amebic liver abscess.[A3] In the rare case of fulminant amebic colitis, it is prudent to add broad-spectrum antibiotics to treat intestinal bacteria that may spill into the peritoneum. Parasites persist in up to 50% of patients who are treated with a nitroimidazole, so treatment should be followed with paromomycin or the second-line agent diloxanide furoate to cure luminal infection.

For liver abscesses, drainage should be considered in patients who do not show a clinical response with shrinkage of the abscess within 5 to 7 days of drug therapy, but it usually is not routinely necessary even for large abscesses. Percutaneous needle aspiration or catheter drainage is the procedure of choice for drainage of a liver abscess. Surgical intervention is occasionally required for drainage of a liver abscess, acute abdomen, gastrointestinal bleeding, or toxic megacolon.

PREVENTION

Vaccines[14] are in the late stages of preclinical development for the prevention of amebiasis in the developing world. Provision of sanitation and clean water and safe sexual practices to prevent fecal-oral transmission are of great importance but not universally effective because of the low infectious dose and chlorine resistance of the cyst.

TABLE 323-2 DRUG THERAPY FOR TREATMENT OF AMEBIASIS

DRUG	ADULT DOSAGE	SIDE EFFECTS
AMEBIC LIVER ABSCESS		
Tinidazole	2 g PO once daily × 5 days	Primarily GI side effects and disulfiram-like intolerance reaction to alcoholic beverages as for metronidazole
or		
metronidazole	750 mg PO tid × 10 days	Primarily GI side effects: anorexia, nausea, vomiting, diarrhea, abdominal discomfort, or unpleasant metallic taste
or		
secnidazole	2-g PO single dose	Disulfiram-like intolerance reaction to alcoholic beverages
or		
ornidazole	500 mg tid × 5 days	Neurotoxicity, including seizures, peripheral neuropathy, dizziness, confusion, irritability
or		
nitazoxanide	500 PO bid × 10 days	Headache, stomach pain, nausea, discolored urine
Followed by a luminal agent		
Paromomycin	30 mg/kg/day PO in 3 divided doses per day × 5-10 days	Primarily GI side effects: diarrhea, GI upset
or		
diloxanide furoate	500 mg PO tid × 10 days	Primarily GI side effects: flatulence, nausea, vomiting
		Pruritus, urticaria
AMEBIC COLITIS		
Metronidazole	750 mg PO tid × 5-10 days	Same as for amebic liver abscess
Plus a luminal agent ([e.g., paromomycin or diloxanide furoate] same as for amebic liver abscess)		
ASYMPTOMATIC INTESTINAL COLONIZATION		
Treatment with a luminal agent (e.g., paromomycin or diloxanide furoate)		

bid = twice a day; GI = gastrointestinal; PO = by mouth; tid = three times a day.
Modified from Haque R, Huston CD, Hughes M, et al. Current concepts: amebiasis. *N Engl J Med*. 2003;348:1565-1573.

TABLE 323-3 FREE-LIVING AMEBAE

ORGANISM	DISEASE	EPIDEMIOLOGY	DIAGNOSIS	CLINICAL COURSE	THERAPY
Naegleria fowleri	Primary amebic encephalitis	Warm freshwater exposure	CSF wet mount for amebae, PCR	Death within 1-2 weeks of onset	Combination therapy with amphotericin B, miltefosine, rifampin, fluconazole, and azithromycin
Acanthamoeba spp	Keratitis	Corneal trauma, usually from contact lens	Corneal scraping for amebae and cysts	Subacute	Polyhexamethylene biguanide, chlorhexidine, propamidine, hexamidine
Acanthamoeba spp	Granulomatous amebic encephalitis	Immunodeficient (organ transplants, HIV/AIDS)	Biopsy of brain or skin abscess—IFA or PCR	Subacute	Combination therapy with miltefosine, pentamidine, an azole (fluconazole or itraconazole), and/or sulfadiazine
Balamuthia mandrillaris	Granulomatous amebic encephalitis	Immunodeficient but also immunocompetent	Biopsy of brain	Subacute	Combination therapy with miltefosine, pentamidine, fluconazole, and sulfadiazine plus either azithromycin or clarithromycin
Sappinia	Amebic encephalitis	Single patient was not immunodeficient			Azithromycin, pentamidine, itraconazole, flucytosine

AIDS = acquired immunodeficiency syndrome; CSF = cerebrospinal fluid; HIV = human immunodeficiency virus; IFA = indirect fluorescent antibody; PCR = polymerase chain reaction.
Modified from Visvesvara GS, Moura H, Schuster FL. Pathogenic and opportunistic free-living amoebae: *Acanthamoeba* spp, *Balamuthia mandrillaris*, *Naegleria fowleri*, and *Sappinia diploidea*. *FEMS Immunol Med Microbiol*. 2007;50:1-26.

PROGNOSIS

Therapy for amebiasis is highly effective. Drug resistance is not reported. Even with liver abscess, the mortality is less than 1% if it is diagnosed and treated early. Death usually results from rupture of the liver abscess into the peritoneum, thorax, or pericardium, but it also may be caused by extensive hepatic damage and liver failure.

FREE-LIVING AMEBAE

Rare infections of the central nervous system can be seen with infection by free-living amebae of the genera *Naegleria, Balamuthia, Acanthamoeba,* and *Sappinia*.[15,16]

Naegleria fowleri is the agent of primary amebic meningoencephalitis,[17] which occurs in previously healthy children and young adults who have swum in fresh water 2 to 5 days before the onset of meningoencephalitis. Cerebrospinal fluid has a polymorphonuclear predominance, and motile amebae can be seen in a wet mount of cerebrospinal fluid. The disease is relentlessly progressive to death in more than 95% of patients,[18] but successful treatment has been reported with a combination of intrathecal and intravenous amphotericin B plus miconazole and oral rifampin.

Acanthamoeba can cause keratitis in individuals with corneal injuries (usually from contact lens use[19]), as well as granulomatous amebic encephalitis in immunocompromised patients. The diagnosis can best be made by a combination of PCR and culture.[20]

Granulomatous amebic encephalitis is caused by *Acanthamoeba, Balamuthia,* and *Sappinia;* it is usually associated with focal neurologic findings and has a subacute course. Miltefosine should be part of combination therapy (Table 323-3).

324 BABESIOSIS AND OTHER PROTOZOAN DISEASES

SAM R. TELFORD, III, AND PETER J. KRAUSE

BABESIOSIS

Babesiosis is a tick-borne, malaria-like disease caused by sporozoan parasites of the genus *Babesia* that infect red blood cells.

EPIDEMIOLOGY

With few exceptions, *Babesia* spp are transmitted by ixodid ticks. Thus, wherever humans are intensely exposed to hard-bodied ticks, babesiosis should be part of the differential diagnosis for a patient presenting with fever and hematologic abnormalities.

Three worldwide epidemiologic patterns are apparent. The first involves the rodent-maintained *Babesia microti*, which is a species complex distributed across the Holarctic. About 2000 cases of *B. microti* babesiosis are reported each year,[1] mostly from the northeastern United States and upper Midwestern states, compared with an average of about 26,000 cases of Lyme disease (Chapter 296), but babesiosis is thought to be underreported. The vector for both *B. microti* and Lyme disease (Chapter 296) is the deer tick, *Ixodes dammini*, also known as northern populations of *I. scapularis*.[2] As a result, concurrent babesiosis and Lyme disease is common. Immunocompetent as well as immunocompromised individuals are at risk. Within the last decade, *B. microti* has been increasingly reported in an expanded distribution in the United States from its original foci in coastal New England and the Upper Midwest, and it is possible that babesiosis cases eventually may be found wherever Lyme disease is intensely zoonotic. In addition, cases of *B. microti* or *B. microti*–like babesiosis have been reported in Australia, Canada, China, Germany, Japan, Mexico, Poland, Spain, South Africa, and Taiwan; the vectors for these have not been definitively identified.

The second pattern is represented by cases of babesiosis due to *Babesia divergens*, *B. divergens*–like, or closely related species (e.g., *Babesia venatorum*) that have been reported from Asia and Europe. Almost all clinical cases in Europe have been in splenectomized patients who reside in sites where castor bean ticks (*Ixodes ricinus*) and deer are common. *Babesia crassa and B. venatorum* babesiosis recently have been found to be endemic in northeastern China, and *B. microti* babesiosis is endemic in southern China on the Myanmar border. A few cases of *Babesia divergens*–like infections (referred to as MO-1) have been described in the United States.

The third pattern of babesiosis involves sporadic cases due to diverse *Babesia* spp, including *Babesia duncani* (WA-1) and CA-type parasites of the western United States; a *Babesia motasi*–like infection (KO-1) in Korea; and unidentified or poorly characterized *Babesia* spp from China, Colombia, Egypt, India, Mexico, Mozambique, and South Africa. Molecular phylogenetic methods provide evidence that human babesiosis may be caused by many of the known *Babesia* spp., as well as by non-*Babesia* piroplasms such as the related parasite *Anthemosoma garnhami*.

The known zoonotic tick vectors (*I. dammini, I. ricinus*) have marked seasonal periods of activity (May to August), and the majority of reported cases are acquired during these times, however, babesiosis may be diagnosed at any time of the year.

More than 250 cases of transfusion-acquired babesiosis due to *B. microti* and three due to *B. duncani* have been reported, but the actual number of cases is thought to be much greater. Babesiosis is one of the most commonly reported transfusion-transmitted diseases (Chapter 162) in the United States, and the number of such cases is increasing, including those ending in death. Cases occur throughout the year, and about 10% of cases occur in nonendemic areas because *Babesia*-infected blood is exported to nonendemic areas or persons become infected in endemic areas and subsequently donate blood in nonendemic areas.[3] A few cases of transplacentally transmitted babesiosis also have been reported.

PATHOBIOLOGY

The pathophysiology of *Babesia* infection is directly related to the development of parasitemia. Peripheral blood parasitemias of 70% or greater have been reported, although most cases sustain parasitemias on the order of 0.5 to 5%. Excessive production of pro-inflammatory cytokines seems to best explain the most common clinical manifestations, which include fever, fatigue, sweats, chills, headache, anorexia, myalgia, nausea, vomiting, and pallor. Such findings are not seen when erythrocyte lysis is due to noninfectious causes, which suggests that the release of merozoites serves as a trigger for the pro-inflammatory cascade. Elevated serum concentrations of TNF as well as of interferon-γ, interleukins 2 and 6, E-selectin, vascular cell adhesion molecule 1, and intracellular cell adhesion molecule 1 are detected during the acute phase of human *B. microti* infection and return to baseline within 3 months after resolution of infection.

Severe illness caused by infection with *Babesia* includes a complex array of metabolic abnormalities and organ dysfunction. Cardiac and pulmonary disease are the most common complications in patients who experience severe *Babesia* infection, with up to 20% of patients suffering from noncardiogenic pulmonary edema. Pro-inflammatory cytokines contribute to the pulmonary complications of *Babesia* infection. Disseminated intravascular coagulation and heart failure are even more frequently observed. It is also likely that lung and other end-organ disease is mediated, at least in part, by vascular stasis.

CLINICAL MANIFESTATIONS

About 25% of *B. microti* infections in adults and 50% of cases in children are subclinical. Most people experience a mild to moderate illness that persists for about 1 week. Manifestations include a gradual onset of malaise, anorexia, fatigue, fever (temperature as high as 40° C), sweats, and myalgia. Nausea, vomiting, headache, shaking chills, emotional lability, depression, hemoglobinuria, and hyperesthesia can also occur. Findings on physical examination may consist of fever, pallor, splenomegaly, and hepatomegaly. Laboratory abnormalities include anemia, thrombocytopenia, and leukopenia. Parasitemia generally ranges from barely detectable on blood smear to 5% in previously healthy people, but it may reach 85% in asplenic and other immunocompromised patients. Serum levels of lactate dehydrogenase, bilirubin, and aminotransferases are commonly elevated in more severe cases. Persistent relapsing illness may occur in highly immunocompromised patients who fail to clear the infection for months or more than a year despite multiple courses of antibiotics.

Severe babesiosis usually manifests as an acute onset of illness with hemoglobinuria, a persistent nonperiodic high fever (temperature of 40° to 41° C), shaking chills, intense sweats, headaches, and myalgia, as well as lumbar and abdominal pain. Vomiting and diarrhea may occur. Pulmonary, renal, or liver failure may develop rapidly. In fatal cases, patients become comatose with multiorgan failure. Severe disease occurs only in individuals with asplenia, malignancy, HIV, organ transplants, immunosuppressive treatment, or age younger than 2 months or older than 50 years. About a third of treated asplenic babesiosis patients without a history of autoimmune disease may suffer warm autoimmune hemolytic anemia (Chapter 146) that requires immunosuppressive treatment.

Cases of babesiosis caused by *B. divergens* tend to be severe, at least in part because they are primarily reported in immunocompromised patients. Almost all European patients who have experienced *B. divergens* infection have been splenectomized, and about a third died. *B. duncani, B. venatorum*, and *B. divergens*–like infections also have often been reported in immunocompromised hosts with a similarly severe course of illness. In contrast, the clinical course of *B. venatorum* infection in 48 immunocompetent patients in northeastern China was similar to that of *B. microti* infection, with full recovery of all patients, including seven patients who were admitted to the hospital.

DIAGNOSIS

The diagnosis of babesiosis is based on epidemiologic and clinical findings and confirmed by laboratory testing. It should be considered in patients who live or travel in *Babesia* endemic regions or who have received a blood transfusion within the previous 6 months and whose clinical findings are consistent with babesiosis.

The two primary laboratory tests for confirmation of babesiosis infection are microscopic visualization of parasites on a Giemsa-stained thin blood smear and the detection of *Babesia* DNA on a polymerase chain reaction (PCR) assay. Microscopy can be performed more rapidly than PCR, so it is especially useful in patients who are severely ill with parasitemia above 1% and who need immediate diagnosis and therapy. PCR has greater sensitivity and is especially useful in cases with lower degrees of parasitemia. For *B. microti* babesiosis (Fig. 324-1), examination of a slide for 10 minutes or as many fields as needed to tally 200 leukocytes (that are not infected but serve as a marker for effort) and repeated smears performed twice a day may be required. Standard Romanowsky stains (Giemsa, Wright) using malaria protocols are optimal. Artifactual inclusions are

ABSTRACT

The health burden due to human babesiosis, which causes a clinical syndrome that is similar to malaria, is increasing as it spreads further into sites where Lyme disease is endemic. Because younger infected individuals are often asymptomatic, babesia can also be transmitted through blood donation, and babesiosis is a major transfusion-transmitted disease. Molecular phylogenetic tools are better defining the global public health importance of babesiosis. Similarly, enteric disease due to other protozoa, particularly the coccidia and microsporidia, may more easily be diagnosed and characterized by molecular methods. New methods for detection are providing more information about the prevalence and incidence of trichomoniasis.

limited mainly to stain precipitates (which can be determined by their presence in the plasma spaces between cells), Howell-Jolly or Heinz bodies (Chapter 143), or platelets superimposed on erythrocytes, which always have a light-colored halo when visualized this way. *Babesia* spp have clearly defined chromatin with a lighter-colored cytoplasm (Fig. 324-2A) and may be mistaken for early malarial trophozoites. Neither malarial nor babesial rings have hemozoin (malarial pigment), so this feature cannot distinguish between the two. Paired piriform parasites, arranged in a *v*, are suggestive of *B. divergens* or *B. divergens*–like infection (Fig. 324-2B). Rings of all sizes may be seen in all species. Multiple parasites may frequently be seen in single erythrocytes, as well as clumps of extracellular parasites. Tetrad forms (Fig. 324-2C) and Maltese cross forms (Fig. 324-2D), which are diagnostic but are rarely seen in *B. microti* babesiosis, seem to be more common with *B. duncani* or CA-type infections.

Serologic testing is useful to help confirm *B. microti* infection, but patients with a positive antibody test should have the diagnosis confirmed by a thin blood smear or PCR to diagnose acute infection.[4] The indirect immunofluorescence test, using antigen from infected hamster red cells, is sensitive and specific and is currently the serologic method of choice. A four-fold rise in *B. microti* antibody titer in paired acute and convalescent serum samples is most useful to corroborate *B. microti* infection. The presence of parasite-specific IgM may suggest that the patient has an acute infection even in the absence of readily demonstrable parasitemia. Serology is not generally useful for *B. divergens* babesiosis (although the immunofluorescence test is generally sensitive and specific), given its fulminant natural history.

Serology for *B. duncani* is complicated by a high rate of false positives, and specificity depends on carefully establishing a diagnostic threshold dilution. Antigens for the other *Babesia* spp infecting humans are not available. Because parasitemia occurs before an antibody response and because the doubling time of *B. divergens* can be as short as 8 hours, serologies are not helpful for prompt decision-making.

The known vectors for human babesiosis are ticks that also transmit the agents of Lyme disease (Chapter 296), human granulocytic anaplasmosis (Chapter 302), *Borrelia miyamotoi* infection (Chapter 297), *Ehrlichia muris*–like infection (Chapter 302), and tick-borne encephalitis virus (Chapter 352). Thus, coinfections should be considered in all patients with babesiosis. Acute illness in patients coinfected with Lyme disease and babesiosis is more severe and more persistent than in patients experiencing Lyme disease alone.

TREATMENT

Treatment should be initiated immediately on the basis of clinical suspicion and initial results on PCR testing or microscopy. However, incidental finding of parasites (e.g., during a manual CBC, or at a blood donation center that proactively performs screening) in an otherwise healthy individual requires monitoring but may not require treatment.

Therapy for mild to moderate *B. microti* infection, which typically occurs in immunocompetent individuals, should consist of the combination of atovaquone (750 mg orally twice daily for 7 to 10 days) and azithromycin (500 to 1000 mg initial dose followed by 250 mg orally daily for 7 to 10 days) (Table 324-1),[5,6] which clears parasitemia as effectively as the combination of clindamycin (600 mg orally every 8 hours for 7 to 10 days) plus quinine (650 mg orally every 8 hours for 7 to 10 days) with fewer side effects. For immunocompromised hosts, the azithromycin dose should be increased to 600 to 1000 mg orally daily for 7 to 10 days. For severe babesiosis (which usually occurs in immunocompromised patients or patients over age 50 years), a 7- to 10-day course of the combination of atovaquone (750 mg orally twice daily) and azithromycin (500 mg intravenously once a day) is recommended. An alternative combination is clindamycin (600 mg every 6 hours intravenously) and quinine (650 mg orally every 8 hours).

Treatment may occasionally fail in high-risk patients or in patients who must discontinue quinine because of side effects, such as severe tinnitus and gastrointestinal distress, or because of antibiotic resistance to atovaquone and azithromycin. A prolonged course of treatment may be required to clear parasitemia in certain immunocompromised patients, including patients with B-cell lymphoma (Chapter 171) or other conditions treated with rituximab, patients with malignancy who also are asplenic (Chapter 154), patients with organ or stem cell transplantation, and patients with HIV/AIDS. In such cases, expert consultation is suggested to design combination therapy for immunocompromised patients with one or more of the following regimens: atovaquone, azithromycin, and clindamycin; atovaquone plus clindamycin; atovaquone/proguanil plus azithromycin; or atovaquone, azithromycin, clindamycin, and quinine. Dosing for these antimicrobial combinations should be based on doses recommended for other infections (informed by allergic history, renal function, and other relevant considerations for the specific patient) and/or from the few case reports for which they have been used. Once an effective combination demonstrates clinical improvement and reduction in parasitemia, it should be continued for

TABLE 324-1 TREATMENT REGIMENS FOR ADULTS PATIENTS WITH BABESIOSIS

PATIENT CATEGORY	TREATMENT REGIMEN
Ambulatory patients: mild to moderate disease	Preferred: Atovaquone (750 mg orally with a fatty meal q12h) plus azithromycin 500 mg orally on day 1), then 250 mg daily for 7 to 10 days Alternative: Clindamycin (600 mg orally q8h) plus quinine sulfate (650 mg orally q8h) for 7 to 10 days*
Hospitalized patients: acute severe disease†	Preferred: Atovaquone (750 mg orally q12h) plus azithromycin (500 mg IV q24h) until symptoms abate, then convert to all oral therapy (see step-down therapy) Alternative: Clindamycin (600 mg IV q6h) plus quinine sulfate (650 mg orally q8h) until symptoms abate, then convert to all oral therapy (see step-down therapy)* If infection relapses, consider an experimental regimen (with combinations that include doxycycline, proguanil, pentamidine, or trimethoprim-sulfamethoxazole) under expert guidance
Hospitalized patients: step-down therapy (transition to oral therapy)	Preferred: Atovaquone (750 mg orally with a fatty meal q12h) plus azithromycin (250 to 500 mg orally q24h). Treatment of acute disease plus step-down therapy typically should total 7 to 10 days. A high dose of azithromycin (500 to 1000 mg orally) should be considered for immunocompromised patients Alternative: Clindamycin (600 mg orally q8h) plus quinine sulfate (650 mg orally q8h).* Treatment of acute disease plus step-down therapy typically requires a total of 7 to 10 days
Highly immunocompromised patients	Start with one of the regimens recommended for hospitalized patients with acute severe disease and follow with one of the step-down regimens, but treat for at least 6 consecutive weeks, including 2 final weeks during which parasites are no longer detected on the peripheral blood smear. When oral azithromycin is used, a 500 to 1000 mg daily dose should be considered. If infection relapses, consider an experimental regimen with combinations that include doxycycline, proguanil, pentamidine, or trimethoprim-sulfamethoxazole under expert guidance

*Clindamycin plus quinine is preferred when parasitemia and symptoms have failed to respond to atovaquone plus azithromycin.

†Exchange transfusion should be considered for patients who have high-grade parasitemia (>10%) or moderate to high-grade parasitemia plus: severe hemolytic anemia or severe pulmonary, renal, or hepatic compromise.

IV = intravenous.

Adapted from Krause PJ, Auwaerter PG, Bannuru RR, et al. Clinical practice guidelines by the Infectious Diseases Society of America (IDSA): 2020 Guideline on Diagnosis and Management of Babesiosis. *Clin Infect Dis*. 2021;72:e49-e64.

at least 6 weeks and 2 weeks beyond the time when *Babesia* can no longer be visualized on blood smear or blood samples become PCR negative. Other drugs have been demonstrated to be effective against *B. microti* in laboratory models (e.g., robenidine, primaquine, artesunate, clofazimine, tafenoquine,[7] and endochin-like quinolones) but await clinical trials.

Partial or complete red cell exchange transfusion (1 to 3 blood volumes) should be considered in addition to antibiotic treatment in severely ill patients with parasitemias in excess of 10%, evidence of severe hemolysis, or organ compromise. Apheresis reduces parasitemia and may help reduce pathogenic circulating inflammatory host factors or products liberated by the parasite, but its effect on patients' outcomes is uncertain.[8]

PREVENTION

Prevention depends on reducing the risk for tick bites. Immunocompromised individuals should be especially careful to use personal protection and may even consider avoiding highly endemic sites such as coastal New England and Long Island in the United States during May through August, when the risk is the greatest. Use of repellants such as DEET or application of permethrin to clothing will greatly reduce tick attachment. Such products should be applied to shoes, socks, and trouser cuffs. Wearing light-colored long pants and tucking the cuffs into socks will also help prevent ticks from gaining access to attachment sites. As with the agent of Lyme disease, ticks must be attached at least 36 to 48 hours before a sufficient inoculum of *Babesia* sporozoites is delivered. Daily examination for attached ticks should be performed; the best method is to feel for new bumps on a soapy body in the shower. Any attached ticks should be promptly removed by simple traction, which is best accomplished with the use of tweezers (see Fig. 302-3).

Community-level prevention should focus on public education about the risks of tick-borne infection, reducing the habitat for ticks (brush removal and landscaping around yards), or reducing the reproductive hosts for the tick. Deer reduction will reduce the abundance of the deer tick vector for *B. microti* babesiosis. Screening blood donations for *B. microti* antibodies and *B. microti* DNA (using PCR) can decrease the risk of transfusion-associated babesiosis.[9]

PROGNOSIS

The case-fatality rate for *B. microti* babesiosis has been estimated to be 6 to 9% in hospitalized patients but may be as high as 20% in immunocompromised hosts, including patients who acquire the infection through blood transfusion. Based on Medicare data, about 1% of patients older than 65 years of age die within 30 days of diagnosis.

Among survivors, long-term sequelae have not been reported if patients were adequately treated. In most patients who complete a full treatment regimen, *B. microti* DNA becomes undetectable by PCR within 3 months. Infection does not, however, imply protective immunity, although subsequent infections are usually limited in duration and intensity. Recrudescent infections have been reported, mainly in immunocompromised individuals.

ENTERIC PROTOZOA

The gastrointestinal and urogenital tracts may contain representatives of the four major groupings of protozoa (amebae, sporozoa, flagellates, and ciliates). Diarrhea and other lower gastrointestinal signs and symptoms may be caused by diverse protozoa. Specific clinical diagnosis is difficult because expert clinical parasitology support is required to determine whether an agent that has been detected in a stool sample is a pathogenic species. However, new point-of-care

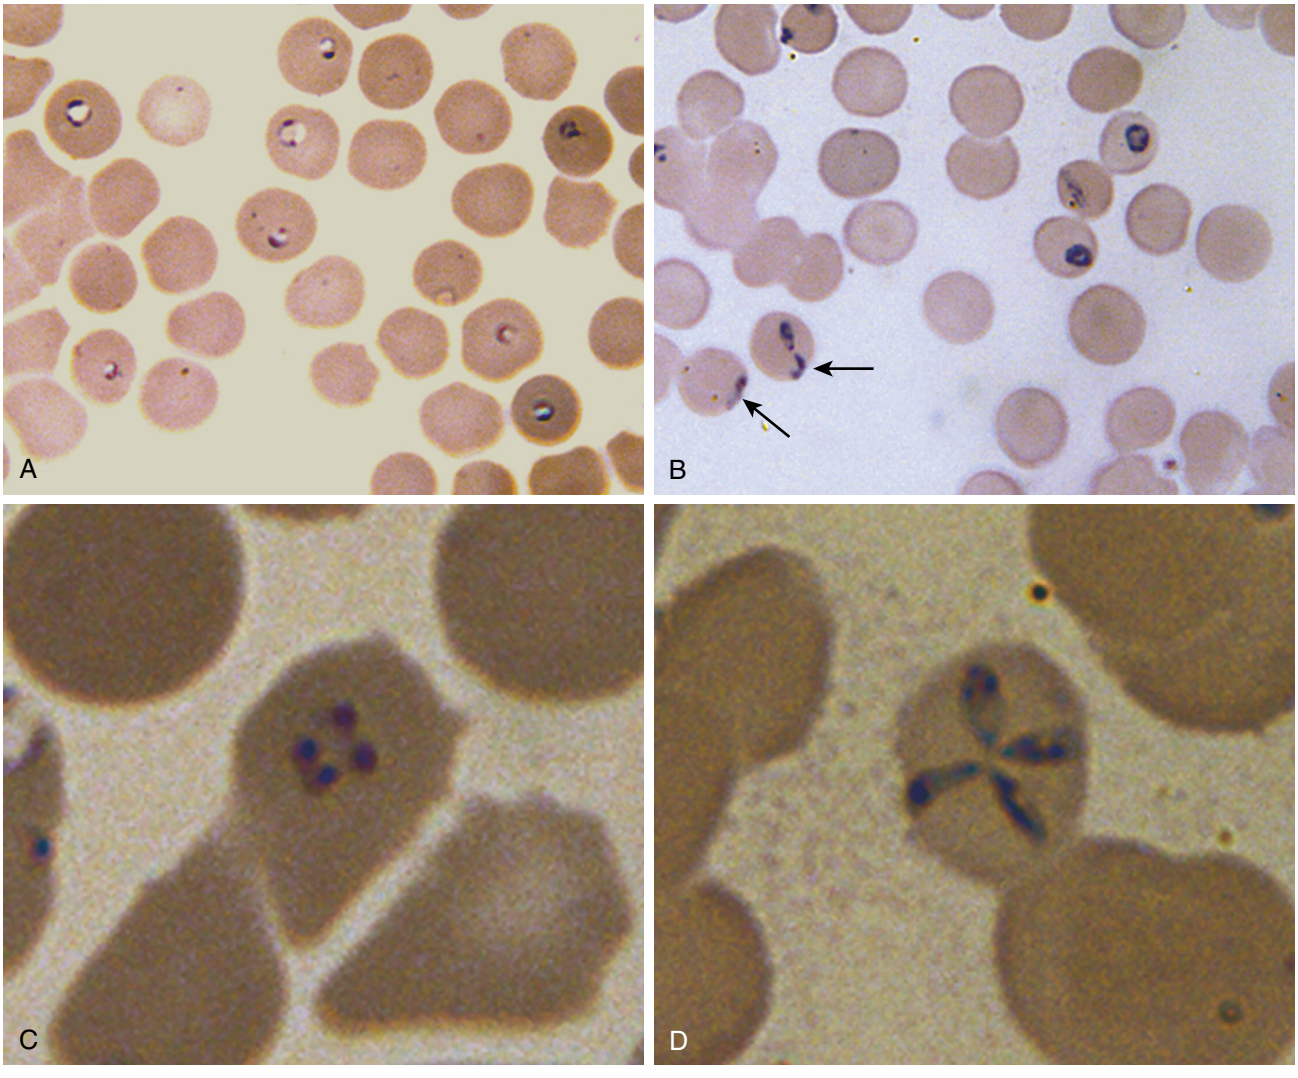

FIGURE 324-2. Diagnosis of *Babesia* infection. A, Typical thin-film field demonstrating ring forms of *B. microti* with vacuole or "whitish" cytoplasm demarcated by a dark-staining, defined chromatin. **B,** *B. divergens*–like (MO-1) with robust rings; accolé form and paired piriform parasites marked by *arrows*. **C,** Tetrad forms of *B. microti*. **D,** MO-1, classic Maltese cross. (Microscope slide from human case of MO-1 kindly provided by Dr. J. F. Beattie, Department of Pathology, The Medical Center, Bowling Green, Ky.)

antigen detection tests, or nucleic acid amplification tests (NAAT) are sensitive and specific when they can be used. Identification is necessary because treatment options differ by the agent. With the exception of *Trichomonas vaginalis* infection (sexually transmitted), all of the enteric protozoa are acquired by the ingestion of food or materials contaminated by human feces; a small subset may have extraintestinal manifestations. Given a shared mode of transmission (fecal-oral), demonstrating the presence of any one of these protozoa within a stool sample from a patient is justification for an intensified search for those that are recognized as clinically significant pathogens (*Entamoeba histolytica* [Chapter 323], *Giardia lamblia/intestinalis* [Chapter 322], *Cyclospora cayetanensis*, *Cystoisospora belli*, and *Cryptosporidium parvum/hominis* [Chapter 321]). Common luminal intestinal protists that are frequently detected during stool analyses for ova and parasites (e.g., *Blastocystis hominis, Dientamoeba fragilis, Iodamoeba bütschlii, Entamoeba coli*, and *Endolimax nana)* are thought to be microbes that interact with the intestinal microbiome (Chapter 257) and that any health impacts are likely because of their tendency to induce or serve as markers for dysbiosis, not because they themselves directly cause clinical manifestations.[10]

Cryptosporidiosis (Chapter 321), giardiasis (Chapter 322), and amebiasis (Chapter 323) are discussed in separate chapters. Trichomoniasis and coccidian enteritis are discussed here because they are relatively common infections.

TRICHOMONIASIS

EPIDEMIOLOGY

Trichomonas vaginalis is among the most prevalent of all pathogenic protozoa and is one of the most common sexually transmitted infections (Chapter 264) in the United States and likely worldwide. The World Health Organization estimates that over 150 million incident cases of trichomoniasis occur annually worldwide, thereby making trichomoniasis more common than chlamydia (about 130 million annual cases; Chapter 294) or gonorrhea (about 90 million cases; Chapter 275).[11] In the United States, the Centers for Disease Control and Prevention estimate 6.9 million incident cases per year,[12] with trichomoniasis infection rates seven-fold higher in Black women as compared with non-Hispanic White women. *T. vaginalis* can be passed from infected mothers to their newborn daughters, but it is seldom symptomatic in girls before menarche. The parasite is able to survive for some time in moist environments, and nonvenereal transmission, although uncommon, can occur. Trichomoniasis, like other sexually transmitted diseases, may increase the likelihood of transmission of HIV (Chapter 353).

PATHOBIOLOGY

T. vaginalis, known colloquially as a flagellate, is classified in the phylum Metamonada and class Parabasalia, along with another human pathogen, *Dientamoeba fragilis* (previously thought to be an ameba). The 10- to 15-µm-long trophozoites multiply by longitudinal binary fission on the epithelial surface of the vagina or urethra as well as in vaginal or urethral secretions and are thereby transmitted by sexual intercourse. No cyst form is known, and the trophozoites are easily killed by drying.

The parabasalids are a phylogenetic sister group to the class Eopharingia, which includes *Giardia* spp. The parabasalids lack mitochondria and are anaerobic; they all have a unique cellular organelle, the hydrogenosome, which is a relic of the mitochondrion and serves as the site of anaerobic pyruvate metabolism. A hemolysin is produced and may cause epithelial damage.

CLINICAL MANIFESTATIONS

As many as 50% of *T. vaginalis* infections in women and the majority of infections in men are asymptomatic. Nonetheless, trichomoniasis is one of three common causes of vaginitis or vaginosis, along with bacterial vaginosis and vulvovaginal candidiasis (Chapter 264).[13]

After an incubation period of 5 to 28 days, trichomoniasis is characterized by a thin gray to yellowish green frothy discharge; vulvovaginal erythema; ectocervical erythema or "strawberry cervix," observable mainly by colposcopy; pH higher than 4.5; increased presence of polymorphonuclear leukocytes; and a positive result of the whiff test, in which a foul fishy odor is intensified on addition of potassium hydroxide. In addition to a frothy discharge, vaginitis can be accompanied by vulvovaginal irritation, dyspareunia, abdominal pain, and dysuria. Symptoms may worsen during menstruation. *T. vaginalis* can frequently be isolated from the male partners of infected women and can produce symptomatic urethritis, generally with a scant urethral discharge. Rarely, *T. vaginalis* is associated with epididymitis, superficial penile ulcerations that are usually located under the prepuce, or prostatitis. Pharyngitis also can occur.[14] *T. vaginalis* infection is not associated with a greater risk of prostate cancer.

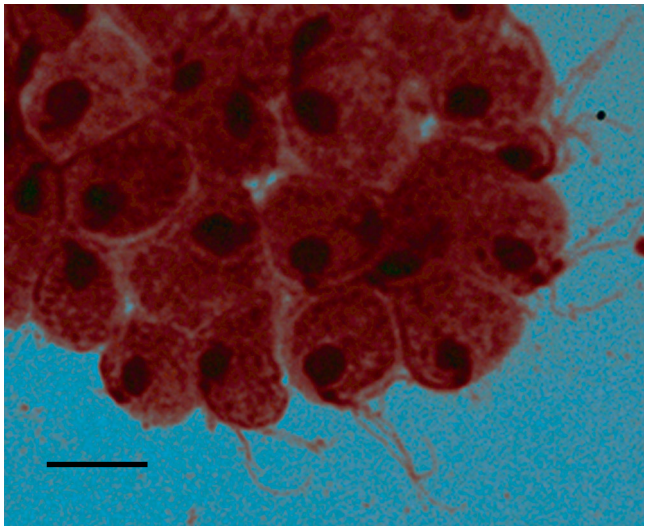

FIGURE 324-3. ***Trichomonas vaginalis*, Giemsa-stained smear of cultivated trophozoites.** (Bright-field microscopy, ×630. Scale bar is 15 µm.)

DIAGNOSIS

All women who seek health care for a vaginal discharge should be specifically tested for evidence of *T. vaginalis* infection. Rapid point-of-care nucleic acid testing of vaginal secretions or a urethral scraping has an excellent sensitivity and specificity[15,16] and is now the test of choice for diagnosis.

T. vaginalis is seen in wet mounts of vaginal secretions in approximately 60% of infected women, thus confirming the diagnosis. Live *T. vaginalis* have a twitching or tumbling motion in wet mounts, and polymorphonuclear leukocytes are usually present. For men, a wet mount of material from a platinum loop scraping of the anterior urethra reveals the organism in approximately 50% of cases. *T. vaginalis* is occasionally identified in Papanicolaou-stained smears; Giemsa stain may also be used (Fig. 324-3).Direct immunofluorescent antibody staining of vaginal secretions is another option. Culture is sensitive and useful if NAAT are not available. *T. vaginalis* is not found in the gastrointestinal tract, and the presence of trichomonads in wet fecal mounts or stained fixed fecal smears (iron hematoxylin or trichrome) most likely represents the commensal *Pentatrichomonas* (formerly *Trichomonas*) *hominis*.

Screening

Screening should be considered for women at high risk for infection (e.g., sex workers) or who are being evaluated for a sexually transmitted disease. HIV-positive women should be screened at least on an annual basis because of a *T. vaginalis*-associated risk for pelvic inflammatory disease (Chapter 264).

TREATMENT

Tinidazole (a single 2-g oral dose in adults) or metronidazole (preferably as 500 mg twice daily for 7 days rather than a single 2-g oral dose)[A1] is the treatment of choice (Chapter 315). Tinidazole is the better tolerated of the two and is more effective as single-dose therapy, which ensures adherence. Both tinidazole and metronidazole have a disulfiram-like effect, and patients who consume alcohol within 24 hours of metronidazole or 72 hours of tinidazole may experience severe nausea, vomiting, and flushing.

Because infection is associated with preterm delivery and low birth weight, pregnant women should be treated for symptomatic trichomoniasis. Metronidazole has low risk during pregnancy, with no reports of teratogenicity or mutagenicity, but tinidazole is not recommended.

Treatment failures with metronidazole and tinidazole are uncommon but well documented. HIV-positive women should be treated for 7 days with 500 mg per day of metronidazole because of frequent recrudescence with the single-dose therapy. Some instances of treatment failure in immune-intact women result from reinfection, others from poor compliance, but some are caused by resistant parasites.[17] A repeated course of metronidazole or tinidazole (2 g orally daily for 7 days) may be tried. If patients remain refractory to appropriate treatment, oral tinidazole (2 g daily for 14 days) should be added to intravaginal tinidazole (500 mg twice daily for 14 days). Clinical improvement also has been documented with intravaginal boric acid (600 mg in gelatin capsules, twice daily for one month).

PREVENTION

Condoms (male or female) reduce risk of acquiring trichomoniasis. Sexual partners should be treated concurrently to prevent reinfection because nearly 20% of male partners are coinfected.

PROGNOSIS

Rare complications include pelvic inflammatory disease (Chapter 264). Infection during gestation may lead to fetal growth retardation. There is no natural or acquired immunity, so reinfection may be common.

COCCIDIAN ENTERITIS

EPIDEMIOLOGY

The coccidia, with 43 genera and more than 1700 recognized species, are well-known veterinary pathogens. *Cyclospora cayetanensis, Cystoisospora belli*, and *Sarcocystis* spp. are causative agents of enteritis in humans. Despite their ubiquity (nearly 200 species have been described), *Sarcocystis* spp have rarely been implicated in cases of human enteritis.

Cyclospora cayetanensis may have both an animal and human reservoir, but *Cystoisospora belli* is thought to be an anthroponosis. Cyclosporiasis is a cause of gastroenteritis in tropical and subtropical areas, with Peru, Mexico, Haiti, Caribbean countries, and Nepal commonly reporting such cases. Outbreaks are invariably traced to contaminated fresh produce, such as raspberries, basil, cilantro, snow peas, or mesclun. Such outbreaks have a distinct seasonality, with most cases presenting during June and July. Cyclosporiasis is commonly diagnosed in international travelers, and large outbreaks have been reported from cruise ships. Cystoisosporiasis has mainly been reported in patients who have the acquired human immunodeficiency syndrome (AIDS)[18] or who are otherwise immunosuppressed. Food or water contaminated with human feces are the source of infection.

Sarcocystis spp are common parasites of mammals, birds, and reptiles.[19] Humans become infected by ingesting undercooked meat or food or water that has been contaminated with animal feces, usually during travel to tropical countries. Humans serve as definitive hosts for *S. suihominis* and *S. hominis*, but when pigs or cattle (intermediate hosts for the two anthroponotic species, respectively) ingest food contaminated with human feces, cysts are formed in their muscles and serve as the source for new human infections.

PATHOBIOLOGY

Oocysts are passed in feces and must sporulate for at least a day (*Cystoisospora belli*) or 5 to 11 days (*Cyclospora cayetanensis*) before attaining infectivity. Sporulated oocysts may persist in the environment for months and retain their infectivity. The infectious dose for *Cyclospora cayetanensis* is estimated to be less than 100 oocysts.

Sporozoites are liberated in the small bowel, where they penetrate enterocytes (for *Cyclospora cayetanensis*, mainly in the jejunum, whereas *Cystoisospora belli* sporozoites may also invade the bile ducts and gallbladder). Both *Cystoisospora belli* and *Cyclospora cayetanensis* have a complicated developmental cycle composed of asexual and sexual stages. The gametes fuse within enterocytes or epithelial cells, and an oocyst wall is deposited around the zygote. This sexual cycle begins about a week after infection, with oocysts sloughing into the bowel lumen and subsequently out of the body through feces. Biopsy specimens from infected patients demonstrate mononuclear and eosinophilic infiltrates in the lamina propria as well as alterations to the morphology of villi.

Humans appear to be intermediate hosts for certain *Sarcocystis* spp. after ingesting undercooked meat containing sporocysts (sarcocysts). Sporozoites are liberated from the sporocysts in the small bowel, enter the vasculature, and form cysts in muscle. The sarcocysts can acutely provoke intense inflammatory infiltrates, thereby resulting in myositis.

CLINICAL MANIFESTATIONS

After an incubation period of approximately 1 week, *Cystoisospora belli* and *Cyclospora cayetanensis* typically produce watery diarrhea, nausea, vomiting, abdominal pain, myalgias, anorexia, and fatigue. Infections may be asymptomatic, and even symptomatic illness is usually self-limited. However, symptoms can be prolonged (10 to 12 weeks) and associated with steatorrhea, flatulence, and substantial weight loss in persons who are immunocompromised, especially patients with AIDS (Chapter 358).[20] *Cystoisospora belli* has been detected in the gallbladder and apparently causes a subclinical infection in immunocompetent individuals, but is associated with acalculous cholecystitis in immunosuppressed patients.

In zoonotic sarcocystosis, parasites migrate to muscle with associated headache, fever, myalgias, weakness, and edema. With *S. nesbitti*, fever and myalgias are the dominant presentation. *Sarcocystis* spp. that appear to be anthroponotic usually colonize the intestinal epithelium but are typically not associated with disease. Rarely, a diarrheal disease may result accompanied by mild fever, chills, and vomiting.

DIAGNOSIS

The diagnosis is confirmed by identifying coccidia in stool samples stained with modified acid-fast or modified safranin preparations or by phase contrast microscopy or bright-field microscopy (using iodine as a contrast medium) of wet mounts (Fig. 324-4). *C. cayetanensis* and *C. belli* may be sensitively detected by fluorescent microscopy of wet mounts. The CDC can help confirm the identification of these enteric protozoa by telediagnosis (sending a digital image of suspicious microscopy findings). PCR is specific and can be sensitive, depending on the mode of DNA extraction. PCR support may be requested from the CDC through state public health departments. *S. nesbitti* and likely other zoonotic *Sarcocystis* spp appear to undergo an aberrant asexual cycle within humans and may

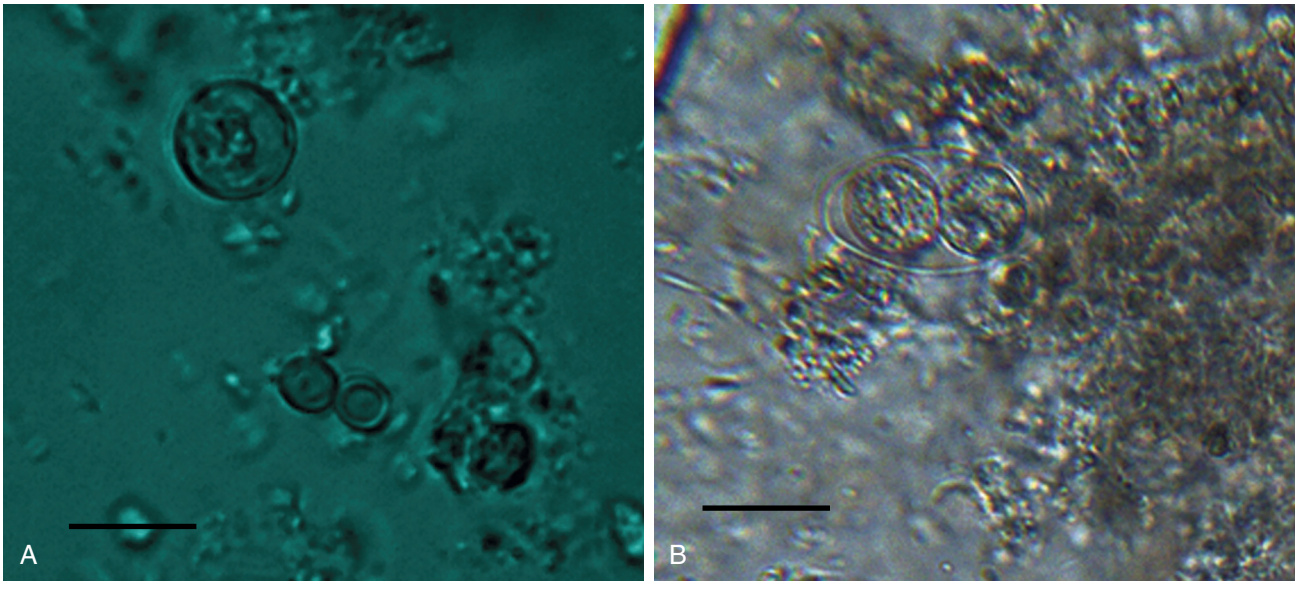

FIGURE 324-4. **Diagnosis of coccidian enteritis. A**, *Cyclospora cayetanensis*, seen on formalin-fixed human feces, unsporulated. (Bright-field microscopy, ×1000 with green contrast filter. Scale bar is 10 μm.) Note the doublet of yeast cells in lower right of the photomicrograph. **B**, *Cystoisospora belli*, seen on formalin-fixed human feces, partially sporulated. (Bright-field microscopy, ×400. Scale bar is 15 μm.)

not produce oocysts to be liberated into the bowel; as a result, diagnosis has required muscle biopsy or demonstration of eosinophilic myositis, sometimes without visualization of the sarcocyst.

TREATMENT

Rehydration is important, as it is for any severe diarrheal disease. *Cystoisospora belli* and *Cyclospora cayetanensis* disease may respond to treatment with 160 mg trimethoprim and 800 mg sulfamethoxazole taken twice daily for 7 to 10 days. HIV-infected patients may require a longer course of therapy.

No specific treatment is established for sarcocystosis, although albendazole (400 mg orally twice daily for 1 month) has been used. Symptomatic relief may be promoted by corticosteroids (e.g., oral prednisolone 100 mg daily for 5 days or intravenous hydrocortisone 100 mg three times a day for 5 days).

PREVENTION

At the community level, preventing the contamination of water and food (mainly vegetables and fruits) by animal or human feces reduces the risk of transmission. Washing vegetables and fruits in water will reduce the potential inoculum but does not eliminate all risk. *Cyclospora cayetanensis* can resist 10 ppm chlorine treatment. The widespread use of trimethoprim-sulfamethoxazole prophylaxis for *Pneumocystis* (Chapter 313) has reduced the incidence of coccidial diarrhea in patients with HIV infection. Sarcocystosis may be prevented by ensuring that meat is well cooked and by freezing meat at -20° C for at least 2 days.

PROGNOSIS

Reactive arthritis (Chapter 254), Guillain-Barré syndrome (Chapter 388), cholecystitis, and cholangitis (Chapter 141) have been reported as complications of coccidian enteritis, mainly in patients with AIDS. Otherwise, treatment appears to eradicate the organism. Whether reinfection may occur is not known. Extraintestinal development of *Cystoisospora belli* and *Cyclospora cayetanensis* suggest the possibility of reinvasion of the bowel with ensuing recrudescence of signs and symptoms, particularly in immunocompromised individuals.

OTHER ENTERIC PROTOZOANS

A number of other protozoa (also called protists) are transmitted by fecal-oral contamination and have been associated with enteric disease (Table 324-1). These enteric protozoa should be considered in the differential diagnosis of patients with persistent diarrhea and abdominal symptoms, particularly patients with a history of recent international travel (Chapter 265).

MICROSPORIDIA

Microsporidia, which have classically been considered to be protozoa but are now known to be obligately intracellular fungi (Cryptomycota), are discussed here because diagnostic parasitology laboratories continue to confirm diagnoses of these agents. Microsporidia are a diverse group of more than 300 species in 160 genera, but only 10 genera have been confirmed as causative agents in human disease. Some of these microsporidia reside in the lumen of the bowel, and others invade and multiply within enterocytes.

Chronic microsporidial diarrhea in HIV patients can contribute to wasting and cachexia. Microsporidia may disseminate to the biliary system and cause cholangitis; dissemination of these organisms in the immunosuppressed may also result in sinusitis or pulmonary disease. Some of the microsporidia cause conjunctivitis or other ocular disease.

OTHER INTESTINAL PROTISTS

Enterocytozoon bieneusi is the second most common "protozoal" cause of diarrhea in HIV patients (after *Cryptosporidium* spp.). *Enterocytozoon bieneusi* spores are shed in the feces and are environmentally resistant. Humans are thought to be the main host but diverse animals have been infected.

Balantidium (Balantioides) coli is the only ciliate known to infect humans.[21] Risk seems to be associated with pigs, which are commonly infected. Transmission is by the fecal-oral route (contaminated food or water). Both trophozoites and cysts are liberated in diarrheal stools, but only the cyst is infectious. Cysts are liberated in the small intestine, and the trophozoites colonize the lumen of the colon. Some trophozoites are invasive and may multiply in the colonic epithelium, where they cause ulceration, inflammation, and malabsorption. Most infection is asymptomatic, but persistent diarrhea and abdominal pain are the main symptoms of disease.

Dientamoeba fragilis and Blastocystis hominis have been associated with diarrhea, but causality remains disputed; indeed, *Blastocystis hominis* has been inadvertently transmitted to patients during fecal transplantation but caused no signs or symptoms.

DIAGNOSIS

A clinical diagnosis is rarely possible because of the nonspecific presentation. Laboratory tests, mainly for ova and parasites in stools, establish the diagnosis. Nucleic acid testing is more sensitive and specific but is not routinely used because primers and probes are not yet available for most of the less common enteric protozoal infections.[22] Expert microscopists are currently required because all of the enteric protozoa may be confused with fecal debris. Laboratory identification is further complicated because coccidian oocysts of animals may be found as pseudoparasites, present because they were ingested with food or water and failed to be digested. Pathogenic protozoa must also be differentiated from commensals such as *Entamoeba coli, Endolimax nana, Iodamoeba bütschlii, Pentatrichomonas hominis, and Chilomastix mesnili*.

TREATMENT

Therapy for microsporidiosis, balantidiasis, and for the signs and symptoms associated with *B. hominis* and *D. fragilis*, if indicated, includes administration of the appropriate antiprotozoal drugs (Table 324-2) (e.g., fumagillin for microsporidia)[23] and rehydration.

TABLE 324-2 TREATMENT OF PROTOZOAN DISEASES OTHER THAN BABESIOSIS

ORGANISM	EPIDEMIOLOGY	MANIFESTATIONS	THERAPY*
Microsporidia† (*Enterocytozoon bieneusi, Encephalitozoon intestinalis, Anncaliia* sp, *Tubulinosema* sp, *Nosema* sp, *Pleistophora* sp, *Vittaforma* sp)	Apparent worldwide distribution	AIDS patients with persistent diarrhea and wasting; self-limited cases in immunocompetent persons	Oral fumagillin (20 mg tid for 2-4 weeks) has been effective for *E. bieneusi*, but it has been associated with thrombocytopenia. Albendazole (400 mg PO bid for 2 weeks) has been effective for *E. intestinalis*. Treatment with HAART may lead to clinical response in HIV-infected patients with microsporidial diarrhea.
Balantidium coli	Primarily an infection of animals, especially pigs, but also affects humans	Asymptomatic or mild and self-resolving; occasionally more severe with abdominal pain, blood, and mucus in stool	Tetracycline (500 mg PO qid for 10 days) Alternative: metronidazole (750 mg PO tid for 5 days) or iodoquinol (650 mg PO tid for 20 days).
Blastocystis hominis	Probably worldwide, including North America; often found concomitantly with *Giardia lamblia*	Pathogenicity is debated; watery diarrhea has been reported but *B. hominis* is common in asymptomatic persons	The need for treatment is debated, but symptomatic improvement has been reported with metronidazole (750 mg PO tid for 10 days); trimethoprim-sulfamethoxazole (160 mg TMP/800 mg SMX PO bid for 7 days); or nitazoxanide (500 mg PO bid for 7 days).
Cyclospora cayetanensis	"Tropical" but imported in produce grown in such sites; animals may serve as reservoir	Acute: watery diarrhea, nausea, vomiting, abdominal pain, myalgias, anorexia, and fatigue. Signs and symptoms may be prolonged in immunocompromised patients and progress to steatorrhea, flatulence, and substantial weight loss.	Rehydration; 160 mg trimethoprim and 800 mg sulfamethoxazole PO bid for 7 to 10 days; immunocompromised patients may require prolonged therapy. Ciprofloxacin 500 mg PO × 7 days is an alternative.

TABLE 324-2 TREATMENT OF PROTOZOAN DISEASES OTHER THAN BABESIOSIS—Cont'd

ORGANISM	EPIDEMIOLOGY	MANIFESTATIONS	THERAPY*
Cystoisospora belli	Global, but most commonly tropical sites; no animal reservoir known	Similar to *C. cayetanensis*	Rehydration; 160 mg trimethoprim and 800 mg sulfamethoxazole orally bid for 7 to 10 days; immunocompromised patients may require prolonged therapy. Pyrimethamine 50-75 mg orally each day for 7-10 days is an alternative to those intolerant of bactrim; leucovorin 10-25 mg orally each day concurrently with the pyrimethamine should be considered to prevent bone marrow suppression
Dientamoeba fragilis	Worldwide distribution; frequently found concomitantly with the pinworm *Enterobius*	Often asymptomatic; diarrhea reported	Paromomycin (25-35 mg/kg body weight per day in 3 doses for 7 days), metronidazole (500-750 mg tid for 10 days), or iodoquinol (650 mg tid for 20 days)

*Based on CDC recommendations, www.cdc.gov/parasites/az/index.html. Accessed July 2, 2021. The dosages and durations are for adults.
†Associated with persistent, severe diarrhea in persons with AIDS.
AIDS = acquired immunodeficiency syndrome; bid = twice daily; HAART = highly active antiretroviral therapy; HIV = human immunodeficiency virus; PO = oral; tid = three times daily.

PROGNOSIS

The diverse presentations of microsporidial diseases (ocular, respiratory, gastrointestinal, biliary, respiratory complications) are influenced by immune status. In immunocompromised patients, symptoms are typically improved by treatment but may relapse when therapy is discontinued. In immune-intact individuals, treatment will usually lead to cure.

325 CESTODES

A. CLINTON WHITE, JR., AND ENRICO BRUNETTI

DEFINITION

The Pathogens

Cestode parasites are members of the animal kingdom, subphylum Cestoda. The organisms are characterized by several life cycle stages, which typically develop in distinct hosts. The adult stage is the tapeworm, which is acquired by ingestion of uncooked tissues that harbor larval forms. After ingestion, the larvae excyst, and the scolex attaches to the intestines. Segments, termed *proglottids*, develop at the base of the scolex and are displaced from the scolex by new proglottids to form a chain or tapeworm. The host in which the tapeworm develops is termed the *definitive host*. The proglottids, which contain male and female sexual organs, produce large numbers of ova. The proglottids or their ova are shed in stools. Humans are the definitive hosts for a number of different tapeworms, including the *Taenia* species, *Dibothriocephalus* species, and *Hymenolepis nana*. Humans also can be an accidental host for the dog and cat tapeworms of the genus *Dipylidium* (Table 325-1).

The intermediate hosts harbor the larval form of the parasite. Infection follows ingestion of the ova. Under the influence of gastric and intestinal fluids, the ova hatch and release the invasive larvae (oncospheres), which migrate to tissues, forming tissue forms. The forms in tissue vary among organisms and may include the cysticercus (a bladder containing a single invaginated scolex), the coenurus (a bladder with multiple scolices), the hydatid (a cystic structure with a germinal layer, which forms numerous protoscolices), or the plerocercoid (a solid form seen in *Spirometra* species). Humans can harbor the intermediate forms of *Taenia solium* (cysticercosis), *Echinococcus granulosus* group (cystic hydatid disease), *Echinococcus multilocularis* (alveolar hydatid disease), and rarely other organisms (Table 325-2). Humans can serve as both the definitive host and an intermediate host for two species, *T. solium* and *H. nana*. In the case of *T. solium*, humans are the obligate host for the tapeworm stage (pork tapeworm) but can also harbor the cystic form (cysticercosis). In the case of *H. nana*, both stages typically develop in a single person, with the cysticercoid form in the intestinal wall and the tapeworm in the lumen.

INTESTINAL TAPEWORM INFECTIONS *DIBOTHRIOCEPHALUS* SPECIES (FISH TAPEWORMS)

Diphyllobothriid tapeworms are large segmented parasites that are acquired by ingestion of undercooked or pickled fish dishes (sushi, sashimi, ceviche, carpaccio, gefilte fish). The tapeworms develop within a few weeks and can live for more than 10 years. These organisms were formerly termed *Diphyllobotrium* species, but recent changes in taxonomy have now reclassified the organisms into several genera and multiple species,[1] including *Dibothriocephalus latus* (formerly *Diphyllobothrium latum*), *Dibothriocephalus nihonkaiensis*, and *Adenocephalus pacificum*.

EPIDEMIOLOGY AND PATHOBIOLOGY

Diphyllobothriid species are found worldwide, and perhaps 20 million people are thought to be infected. Major foci include Russia, Japan, and South America. The disease was formerly highly endemic in Scandinavia, where it is now rarely diagnosed.

In most cases, infection has little impact on the host. However, one species, *D. latus*, contains vitamin B_{12} receptors on the surface of the tapeworm and can out-compete the host, thereby leading to vitamin B_{12} deficiency (Chapter 150). This manifestation has been described only in Scandinavia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In most infected persons, Diphyllobothriid species produce few or no symptoms. Some individuals may complain of gastrointestinal symptoms (abdominal discomfort, nausea, weight loss). The main clinical manifestation is the observation of proglottids being passed in stool. Pernicious anemia (Chapter 150) with symptoms of anemia or peripheral neuropathy may develop with *D. latus* infection. The diagnosis depends on observation of the characteristic operculated eggs in stool.

TREATMENT AND PREVENTION

A single oral dose of praziquantel (5 to 10 mg/kg) is usually adequate for therapy (Table 325-3). Niclosamide can be used as an alternative (2 g [adults] or 50 mg/kg [children] in a single dose chewed and swallowed), but it is not available in the United States. Parasites in fish can be killed by cooking (>56° C, >5 minutes) or freezing (−20° C, 24 hours). Infected fish also may be identified by inspection.

325 CESTODES

A. CLINTON WHITE, JR., AND ENRICO BRUNETTI

DEFINITION

The Pathogens

Cestode parasites are members of the animal kingdom, subphylum Cestoda. The organisms are characterized by several life cycle stages, which typically develop in distinct hosts. The adult stage is the tapeworm, which is acquired by ingestion of uncooked tissues that harbor larval forms. After ingestion, the larvae excyst, and the scolex attaches to the intestines. Segments, termed *proglottids*, develop at the base of the scolex and are displaced from the scolex by new proglottids to form a chain or tapeworm. The host in which the tapeworm develops is termed the *definitive host*. The proglottids, which contain male and female sexual organs, produce large numbers of ova. The proglottids or their ova are shed in stools. Humans are the definitive hosts for a number of different tapeworms, including the *Taenia* species, *Dibothriocephalus* species, and *Hymenolepis nana*. Humans also can be an accidental host for the dog and cat tapeworms of the genus *Dipylidium* (Table 325-1).

The intermediate hosts harbor the larval form of the parasite. Infection follows ingestion of the ova. Under the influence of gastric and intestinal fluids, the ova hatch and release the invasive larvae (oncospheres), which migrate to tissues, forming tissue forms. The forms in tissue vary among organisms and may include the cysticercus (a bladder containing a single invaginated scolex), the coenurus (a bladder with multiple scolices), the hydatid (a cystic structure with a germinal layer, which forms numerous protoscolices), or the plerocercoid (a solid form seen in *Spirometra* species). Humans can harbor the intermediate forms of *Taenia solium* (cysticercosis), *Echinococcus granulosus* group (cystic hydatid disease), *Echinococcus multilocularis* (alveolar hydatid disease), and rarely other organisms (Table 325-2). Humans can serve as both the definitive host and an intermediate host for two species, *T. solium* and *H. nana*. In the case of *T. solium*, humans are the obligate host for the tapeworm stage (pork tapeworm) but can also harbor the cystic form (cysticercosis). In the case of *H. nana*, both stages typically develop in a single person, with the cysticercoid form in the intestinal wall and the tapeworm in the lumen.

INTESTINAL TAPEWORM INFECTIONS *DIBOTHRIOCEPHALUS* SPECIES (FISH TAPEWORMS)

Diphyllobothriid tapeworms are large segmented parasites that are acquired by ingestion of undercooked or pickled fish dishes (sushi, sashimi, ceviche, carpaccio, gefilte fish). The tapeworms develop within a few weeks and can live for more than 10 years. These organisms were formerly termed *Diphyllobotrium* species, but recent changes in taxonomy have now reclassified the organisms into several genera and multiple species,[1] including *Dibothriocephalus latus* (formerly *Diphyllobothrium latum*), *Dibothriocephalus nihonkaiensis*, and *Adenocephalus pacificum*.

EPIDEMIOLOGY AND PATHOBIOLOGY

Diphyllobothriid species are found worldwide, and perhaps 20 million people are thought to be infected. Major foci include Russia, Japan, and South America. The disease was formerly highly endemic in Scandinavia, where it is now rarely diagnosed.

In most cases, infection has little impact on the host. However, one species, *D. latus*, contains vitamin B_{12} receptors on the surface of the tapeworm and can out-compete the host, thereby leading to vitamin B_{12} deficiency (Chapter 150). This manifestation has been described only in Scandinavia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In most infected persons, Diphyllobothriid species produce few or no symptoms. Some individuals may complain of gastrointestinal symptoms (abdominal discomfort, nausea, weight loss). The main clinical manifestation is the observation of proglottids being passed in stool. Pernicious anemia (Chapter 150) with symptoms of anemia or peripheral neuropathy may develop with *D. latus* infection. The diagnosis depends on observation of the characteristic operculated eggs in stool.

TREATMENT AND PREVENTION

A single oral dose of praziquantel (5 to 10 mg/kg) is usually adequate for therapy (Table 325-3). Niclosamide can be used as an alternative (2 g [adults] or 50 mg/kg [children] in a single dose chewed and swallowed), but it is not available in the United States. Parasites in fish can be killed by cooking (>56° C, >5 minutes) or freezing (−20° C, 24 hours). Infected fish also may be identified by inspection.

ABSTRACT

Cestode infections are neglected zoonotic infections that have widespread distributions. Neurocysticercosis is a common cause of neurologic disease in endemic countries. Diagnosis and management vary with the number of parasites and site of infection. Recent advances include the use of combination antiparasitic therapy for multiple parenchymal cysts. Cystic echinococcal disease requires careful staging, and optimal management requires attention to the stage of disease. Intestinal tapeworms are also a common infection worldwide.

Taenia
neurocysticercosis
hydatid disease
Echinococcus

TABLE 325-1 COMMON HUMAN TAPEWORM INFECTIONS

ORGANISM	INTERMEDIATE HOST	COMMON NAME	CLINICAL PRESENTATION	TREATMENT
Dibothriocephalus species	Fish	Fish tapeworm	Passing segments, pernicious anemia	Praziquantel, niclosamide
Hymenolepis nana	Humans	Dwarf tapeworm	Asymptomatic, diarrhea	Praziquantel, niclosamide
Taenia saginata	Cattle	Beef tapeworm	Asymptomatic, passing segments	Praziquantel, niclosamide
Taenia asiatica	Pigs	Asian tapeworm	Asymptomatic, passing worms	Praziquantel, niclosamide
Taenia solium	Pigs	Pork tapeworm	Asymptomatic, passing segments	Praziquantel, niclosamide
Dipylidium caninum	Fleas	Dog tapeworm	Passing segments	Praziquantel, niclosamide

TABLE 325-2 HUMAN LARVAL CESTODE INFECTIONS

ORGANISM	COMMON NAME	ORGANS INVOLVED
Taenia solium	Cysticercosis	Brain, spinal fluid, eye, muscle
Echinococcus granulosus group	Cystic hydatid disease	Liver, lung, other
Echinococcus multilocularis	Alveolar hydatid disease	Liver
Taenia multiceps, Taenia species	Coenurosis	Brain, eyes
Spirometra species	Sparganosis	Subcutaneous tissue, viscera

TABLE 325-3 ORAL THERAPY FOR INTESTINAL TAPEWORM INFECTIONS

	PRAZIQUANTEL	NICLOSAMIDE	NITAZOXANIDE
Dosage			
Adults	5-10 mg/kg for all age groups (15-25 mg/kg for *Hymenolepis nana*)	2 g (4 tablets)	500 mg
Children >34 kg		1.5 g (3 tablets)	200 mg
Children 11-34 kg		1 g (2 tablets)	100 mg
Administration	Taken as a single dose	Taken as a single dose; tablets must be chewed and swallowed	Taken twice a day for 3 days
Side effects	Mild but frequent, including dizziness, myalgias, nausea, vomiting, diarrhea, abdominal pain	Nausea, vomiting, abdominal pain, diarrhea, drowsiness, dizziness, headache, pruritus	
Pregnancy		No known mutagenic effects; considered safe if indicated	

HYMENOLEPIS NANA

Hymenolepis nana is the human dwarf tapeworm. *Hymenolepis diminuta*, a rat tapeworm, can also cause human infection.

EPIDEMIOLOGY AND PATHOBIOLOGY

H. nana is prevalent worldwide, with estimates of at least 50 to 75 million people infected. Infection follows ingestion of ova. The larvae are released, invade, and develop into cysticercoid forms in the intestinal villi. After a few days, the cysticercoids mature, invade the lumen, are transformed into a scolex, and form small tapeworms (up to 5 cm long), which begin producing eggs within 2 to 3 weeks. Autoinfection either in the intestines or by the fecal-oral route can lead to heavy infection.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most infections are asymptomatic. However, some children may be infected by hundreds or thousands of worms, which can cause abdominal pain, loose stools, diarrhea, and malabsorption. Diagnosis depends on observation of the characteristic eggs in stool. More than one specimen may be required.

TREATMENT AND PREVENTION

Praziquantel (15 to 25 mg/kg as a single oral dose) is usually effective in treating *H. nana* infection, but it may need to be repeated in heavy infection (see Table 325-3). Nitazoxanide (100 mg by mouth twice daily for 3 days for children 1 to 3 years of age, 200 mg by mouth twice daily for 3 days for children 4 to 11 years of age, and 500 mg by mouth twice daily for 3 days for older children and adults) is a reasonable alternative therapy; efficacy is about 75 to 82%. Niclosamide also can be used as an alternative, but it must be continued for 7 days. Transmission is by the fecal-oral route and can be prevented by improved hygiene. Mass chemotherapy has been used to control infection in some populations.

DIPYLIDIUM CANINUM

Dipylidium caninum is a common tapeworm of dogs and cats. Dogs are infected by ingestion of fleas, which carry the cysticercoid form in their body cavities. The tapeworms can also develop in children who have ingested the fleas. It is widespread worldwide, but human infections are unusual.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Infection may be asymptomatic. In some cases, the motile proglottids may be noted in stool. The proglottids are similar in size and shape to rice grains. Diagnosis depends on identification of the ova in stool or identification of the proglottids.

TREATMENT AND PREVENTION

There are no controlled trials of treatment for *Dipylidium* infection, but infection is likely to respond to regimens used for other tapeworms (see Table 325-3). The main measure for prevention is treatment of pets for fleas and tapeworms.

TAENIA SAGINATA

Taeniasis refers to infection with the tapeworm form of one of three *Taenia* species. *T. solium* and *Taenia asiatica* are acquired from ingestion of undercooked pork. *Taenia saginata*, called the beef tapeworm, is a common intestinal infection worldwide; cattle, which are the intermediate hosts, harbor the tissue cysticerci in their muscle. Humans, which are the obligate definitive host, harbor the tapeworm form.

EPIDEMIOLOGY AND PATHOBIOLOGY

T. saginata is common worldwide in areas where cattle are raised and human fecal material contaminates the pastures. Approximately 45 to 60 million people are thought to be infected. Infections are found on most continents. Very high rates (>20% of the population) have been noted in east Africa, Bali, and Tibet, but infection is also endemic in the Middle East, the Americas, and Europe. *T. saginata* is also common in other parts of Asia.

T. saginata tapeworms are acquired by ingestion of undercooked beef. The scolex attaches to the intestinal wall, and proglottids form at the base of the scolex. The proglottids gradually enlarge as they are displaced from the scolex by newer proglottids. The chain of proglottids can reach a length of up to 30 feet. The terminal proglottids are shed periodically in the stool. Terminal proglottids are typically off-white, 2 to 3 cm long, 0.5 to 1 cm wide, and 1 to 2 mm thick.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Mild symptoms (e.g., nausea, abdominal discomfort, anorexia, and pruritus) may be noted. The motile proglottids may cause discomfort as they exit the anus or may be noted in stool.

Ova, which may be noted in stool, are 40 µm in diameter and are surrounded by brown radial striations; the embryos have six hooks. However, the ova of the three *Taenia* species are morphologically indistinguishable. The proglottids can be distinguished from those of *T. solium* by counting the number of uterine branches (≥14 branches suggests *T. saginata*). However, the proglottids of *T. saginata* cannot be readily distinguished from *T. asiatica*.

TREATMENT, PREVENTION, AND PROGNOSIS

Taeniasis can be treated with praziquantel in a single dose (see Table 325-3).[2] Single doses of niclosamide are effective, and nitazoxanide has also been used for *T. saginata*. Taeniasis can be prevented by inspection of beef. Also, cooking to 56° C for 5 minutes or freezing at −20° C for 7 to 10 days destroys the infective larvae. Symptoms are self-limited and resolve with or without treatment.

TAENIA ASIATICA

T. asiatica is a cause of taeniasis in Asia, termed *Asian taeniasis*. Infection is acquired by ingestion of undercooked viscera from pigs. Pigs are infected by ingestion of the ova from tapeworm carriers. *T. asiatica* has been widely described in China, Taiwan, Korea, Indonesia, and Southeast Asia. The clinical manifestations, diagnosis, treatment, and prevention of *T. asiatica* infection are similar to those noted for *T. saginata* infection.

TAENIA SOLIUM

T. solium, also known as the pork tapeworm, can cause both tapeworm infection and larval infection termed *cysticercosis*. *T. solium* tapeworm infections are caused by ingestion of infected undercooked pork.

EPIDEMIOLOGY AND PATHOBIOLOGY

T. solium is common worldwide in areas where pigs are raised and where pigs have access to human fecal material. Only a few million people are thought to harbor the tapeworm form. Pork tapeworm infection is highly endemic in Latin America, sub-Saharan Africa, south, east, and southeast Asia.

T. solium tapeworms are acquired by ingestion of undercooked pork. The scolex evaginates and attaches to the intestinal wall, and proglottids form at the base of the scolex. The proglottids gradually enlarge as they are displaced from the scolex by newer proglottids. The adult worms are often 10 to 20 feet long. Within each mature proglottids, thousands of microscopic ova develop. The terminal proglottids are shed periodically in the stool. The ova are either excreted into the stool or shed with the proglottids. By contrast, ingestion of the ova results in development of larval infection, termed cysticercosis (see later). Thus, the tapeworm carrier poses a risk of self-infection as well as infection to other people. Terminal proglottids are typically off-white, 2 cm long, 0.5 to 1 cm wide, and 1 to 2 mm thick.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Mild symptoms (e.g., nausea, abdominal discomfort, anorexia, and pruritus) may be noted. The proglottids may be seen in stool. Diagnosis is made by the finding of ova in stool. The ova are 40 µm in diameter, surrounded by brown radial striations, and embryos have six hooks and are morphologically indistinguishable from the other *Taenia* species.

TREATMENT AND PREVENTION

Taeniasis can be treated with praziquantel in a single (5 to 10 mg/kg) dose. However, praziquantel should be used with caution in areas where cysticercosis is prevalent and avoided in patients who have symptoms suggestive of neurocysticercosis because it can precipitate symptoms such as seizures. A single dose of niclosamide (see Table 325-3) is also effective and safe in those with occult cysticercercosis.

Taeniasis can be prevented by inspection of pork. Also, cooking to 56° C for 5 minutes or freezing at −20° C for 7 to 10 days destroys the infective larvae. Current control measures include mass chemotherapy for entire populations as well as chemotherapy and vaccination of pigs (see Cystercercosis below).

TISSUE CESTODE (CYST) INFECTION

Taenia solium (Cysticercosis)

DEFINITION

T. solium is the cause of human larval infection termed cysticercosis.[3] The normal hosts for the larval (cysticercus) forms are pigs. When ingested by pigs, the ova hatch, releasing the invasive larvae (termed *oncospheres*), which invade the intestines, migrate to tissues (especially muscle), and mature into cysticercus forms within the tissues. The cysticercus consists of a thin translucent bladder that contains an invaginated scolex, which is poised to form a tapeworm after being ingested by a human host. The ova are also infectious to people, including the tapeworm carrier. The sticky ova attach to the hands of the tapeworm carrier and are transmitted by the oral route to the carrier or close contacts. After ingestion, the ova can migrate to tissues and form cysts (cysticercosis). The presence of cysticerci in the central nervous system is termed *neurocysticercosis*. Neurocysticercosis includes cysticerci in the brain parenchyma (parenchymal neurocysticercosis) and cysticerci in the ventricles, subarachnoid space, spine, and eye (extraparenchymal neurocysticercosis).

EPIDEMIOLOGY

Cysticercosis is found in all regions of the world where pigs are raised with access to human fecal material. Cysticercosis is widespread in rural areas of Latin America, where more than 10% of the population in endemic villages may have neuroimaging abnormalities consistent with neurocysticercosis. Cysticercosis is also widespread in sub-Saharan Africa, India, Nepal, Southeast Asia, and parts of China. In India, the most common manifestation of neurocysticercosis is seizures and a single enhancing lesion. In the United States, over 2000 cases are diagnosed each year, with most cases occurring in immigrants from pig-raising villages in Mexico and Latin America. However, there are also imported cases from Asia and a few locally acquired infections.

PATHOBIOLOGY

For cysticercosis, the pathogenesis and pathophysiology vary with the location of the cysticerci and the host inflammatory response. Cysticerci in the brain parenchyma initially suppress the host inflammatory response. After a silent period, estimated to be several years, the cysticerci lose the ability to suppress the host inflammatory response, thereby leading to parenchymal inflammation, which typically is manifested by seizures. The cysticerci induce a granulomatous response, which gradually degrades the parasites. In some cases, the lesions resolve. In other cases, however, degradation leads to formation of calcified granulomas. These calcified lesions may intermittently become inflamed (as evidenced by edema or contrast enhancement on magnetic resonance imaging [MRI] scan) and may cause recurrent seizures during a period of years.

CLINICAL MANIFESTATIONS

The clinical manifestations vary with the location of the cysticerci and the associated host response (Fig. 325-1).[4,5] In some cases, cysticerci develop within the ventricles of the brain and can mechanically cause obstructive hydrocephalus. Cysticerci in the subarachnoid space may cause a chronic arachnoiditis, or mass effect. Cysticerci can also develop in the spine (manifested as radiculitis), eye, subcutaneous tissue, and muscle.

All forms of disease may be associated with headaches. In general, parenchymal cysticerci are associated with seizures, whereas ventricular and subarachnoid cysticercosis are associated with hydrocephalus.

Single Enhancing Lesion

A single enhancing lesion is the most common manifestation of cysticercosis in India and the United States. Patients typically present with headache or seizures, which can be focal or focal with secondary generalization. Many will have a single seizure or a few seizures during the period when the cysticercus is degenerating, but the duration of seizures is eventually self-limited in most cases. However, some cases progress to develop calcified lesions, which are a risk factor for recurrent seizures.

Multiple Parenchymal Cysticerci

In patients who have multiple lesions, the main presentation is with seizures, associated with parenchymal inflammation. In contrast to patients who have only a single lesion, seizures are more likely to recur.

Calcified Lesions

Many patients do not present until after they have calcified lesions. Patients with calcified lesions may develop recurrent seizures during a period of years. Some cases are associated with the development of mesotemporal sclerosis and refractory epilepsy (Chapter 372).[6]

Ventricular Cysticerci

The cysticerci typically are manifested by obstructive hydrocephalus.[7] The patient may present with headache, nausea and vomiting, dizziness, altered

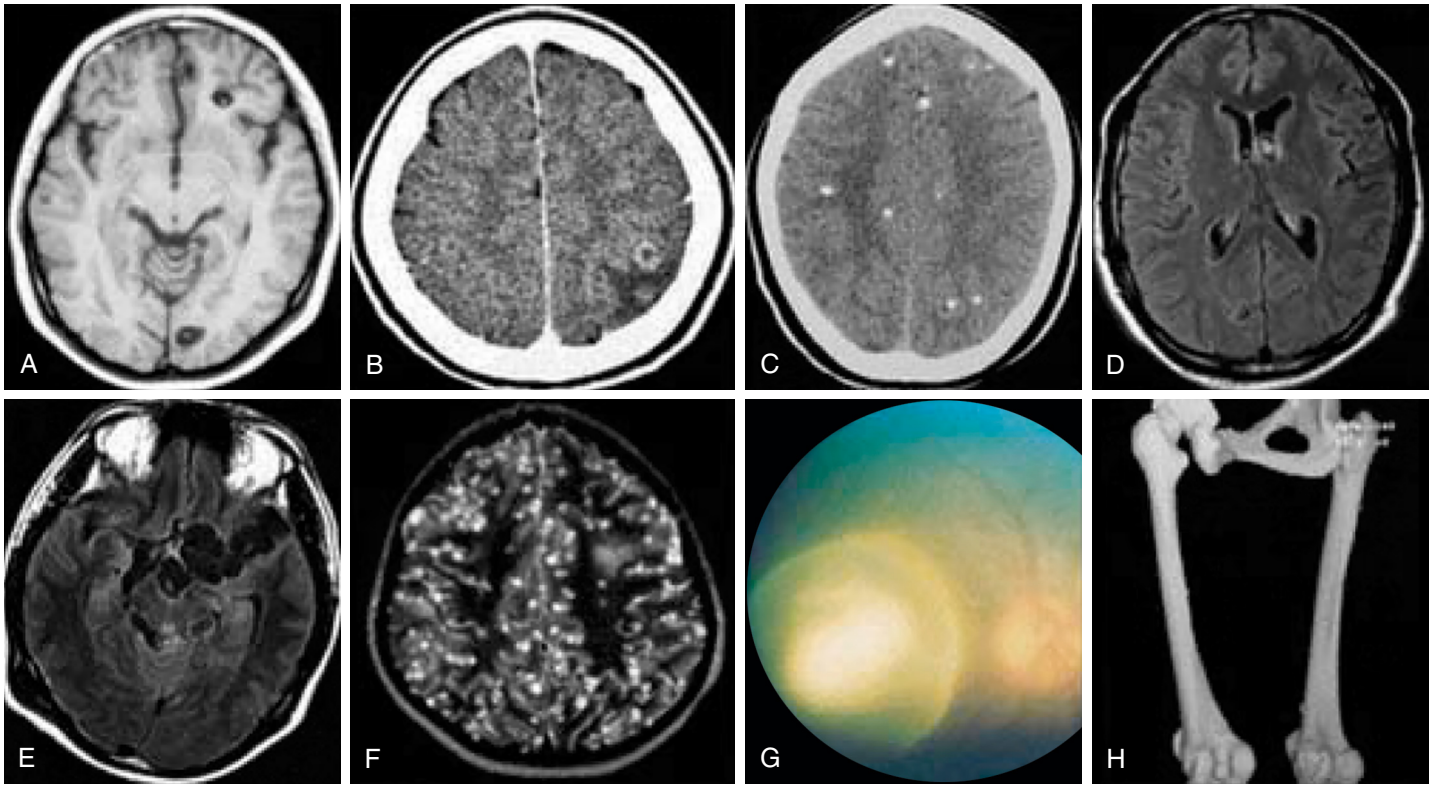

FIGURE 325-1. **Human neurocysticercosis can be classified on the basis of neuroimaging studies. A,** Multiple cystic lesions. **B,** Single enhancing lesion. **C,** Multiple calcifications. **D,** Intraventricular cysticerci. **E,** Subarachnoid cysticerci. **F,** Diffuse infection with cerebral edema, termed cysticercal encephalitis. **G,** Ocular cysticerci. **H,** Diffuse muscle calcifications. mental status, or papilledema with altered vision. This presentation is a medical emergency and can be fatal if it is not treated.

Subarachnoid Cysticerci

Cysticerci in the basilar cisterns are often accompanied by cysticerci in other locations, including parenchymal cysticerci or calcifications, ventricular cysticerci, and spinal or ocular cysticerci; patients may present with disease attributable to cysticerci at these sites. Cysticerci in the basilar cisterns are particularly prone to cause arachnoiditis. Manifestations of arachnoiditis may include vascular involvement (large- or small-vessel strokes), meningeal signs, or communicating hydrocephalus (headaches, nausea, vomiting, dizziness, and altered mental status).[8] This form of neurocysticercosis is associated with a high fatality rate.[9]

DIAGNOSIS

The major clinical manifestations of neurocysticercosis (e.g., seizures and hydrocephalus) are not specific, and it is difficult to identify the parasites. The main tools used to diagnose neurocysticercosis are neuroimaging studies. Computed tomography (CT) scans are sensitive for identifying parenchymal calcifications, which appear as 2- to 5-mm nodules. CT may also reveal parenchymal cysticerci or obstructive hydrocephalus. Magnetic resonance imaging scans are more sensitive for identification of the cysticerci, especially in the subarachnoid space and ventricles. Three-dimensional sequences such as fast imaging employing steady-state acquisition are particularly effective for identifying ventricular and subarachnoid cysticerci. The cysticerci are typically round and 1 to 2 cm in diameter. The cyst fluid is usually isodense with spinal fluid. In uninflamed cysticerci, the walls may not be visible. However, most cases demonstrate enhancement of the cyst walls or surrounding tissues and associated edema. In some cases, the scolex may be visible as a 1- to 2-mm solid nodule, cylinder, or spiral on the side of the cystic lesions.

Polymerase chain reaction antigen detection assays are sensitive and specific.[10] An immunoblot assay using semipurified membrane glycoproteins is highly specific but has poor sensitivity in patients who have single enhancing lesions or just calcifications.

TREATMENT

Treatment varies with the clinical manifestations and form of infection. Seizures should be treated with antiepileptic drugs (Chapter 372). Phenytoin and carbamazepine are typically used and can control the seizures. In patients who present with hydrocephalus, surgery to re-establish cerebrospinal fluid flow is the critical initial step in management.

The role of antiparasitic drugs (Chapter 315) varies with the form of infection. Parenchymal cystic lesions resolve more rapidly with fewer generalized seizures when patients are treated with both corticosteroids (e.g., dexamethasone 0.1 mg/kg/day in three daily doses) and albendazole (15 mg/kg/day in two daily doses) for 7 to 10 days compared with placebo.[11] Praziquantel (50 to 100 mg/kg/day in three daily doses) can be used as an alternative. Data also suggest using the two drugs in combination (praziquantel 50 mg/kg/day plus albdendazole 15 mg/kg/day) in patients who have more than two parenchymal cysticerci. For a single enhancing lesion, radiologic resolution is slightly more rapid with fewer seizures when patients are treated with corticosteroids plus albendazole at doses noted above.[A1] Higher-dose corticosteroids (e.g., dexamethasone 8 mg/day in divided doses for 28 days followed by a taper) may decrease seizures near the time of antiparasitic treatment, but the differences are not dramatic. Patients who have only calcified lesions do not harbor viable parasites, so the main goal is to control symptoms (e.g., antiepileptic drugs for those with seizures; Chapter 372).

For patients with cysticerci in the ventricles, management usually involves removal by neuroendoscopy for lateral and third ventricular cysticerci and by either microsurgical dissection or neuroendoscopy for fourth ventricular cysticerci. An alternative approach for ventricular cysticerci is placement of a ventriculoperitoneal shunt. Chronic corticosteroids and antiparasitic drugs may decrease the rate of shunt failure (see doses and durations for subarachnoid disease), which usually results from clogging of the shunts by the cysticerci or proteinaceous debris. In the absence of controlled trials, expert opinion supports treatment of subarachnoid cysticercosis with prolonged courses of antiparasitic drugs (e.g., albendazole 15 mg/kg in two divided doses for months), higher doses of albendazole (up to 30 mg/kg/day in 28-day pulses), or combinations of albendazole (15 mg/kg/day in two daily doses) plus praziquantel (50 mg/kg day in three daily doses). Chronic anti-inflammatory medications (e.g., prednisone 1 mg/kg/day for at least the first month) are also critically important.[12] Patients who will be treated with chronic corticosteroids should be screened for *Mycobacterium tuberculosis* (Chapter 299) and *Strongyloides* (Chapter 327)

infections before initiation of therapy. Methotrexate (beginning at 7.5 mg/week, can be increased to a maximum of 20 mg/week) is increasingly recommended as a steroid-sparing agent. Patients with hydrocephalus should be treated by cerebrospinal fluid diversion (e.g., ventriculoperitoneal shunting). Before treatment with antiparasitic drugs, patients should undergo a funduscopic examination. Intraocular parasites may develop brisk inflammatory responses after treatment with antiparasitic drugs. Because this inflammation could lead to blindness, most authorities recommend extraction of the parasites before antiparasitic therapy. However, there are also reports of treatment of intraocular parasites with antiparasitic drugs.

PREVENTION

Although transmission of *T. solium* is potentially preventable, population-wide eradication efforts have proved very difficult. Nevertheless, transmission of *T. solium* infection can be interrupted in highly endemic regions by a program emphasizing mass antiparasitic treatment of the human population with niclosamide (2 g in a single dose) or praziquantel (5 to 10 mg/kg in a single dose), treatment of pigs with oxfendazole, plus vaccination of piglets.[A2,13] Alternatively, prevention can target rings around infected pigs.[A3]

PROGNOSIS

The prognosis varies significantly among the different forms of neurocysticercosis. Parenchymal enhancing lesions and parenchymal cystic lesions will eventually resolve over months to years. Patients who have or develop calcifications are at lifelong risk for recurrent seizures. Patients who have ventricular or subarachnoid disease are at high risk for morbidity and mortality, but can do well with optimal management.

CYSTIC HYDATID DISEASE (*ECHINOCOCCUS GRANULOSUS* GROUP)

DEFINITION

Cystic echinococcosis, also called cystic hydatidosis, is caused by the larval stage of cestodes of a number of different species (*Echinococcus granulosus, Echinococcus candadensis*) and 10 distinct genotypes of the *E. granulosus* complex.[14] In humans, the clinical manifestations range from asymptomatic infection to severe, potentially fatal disease.

EPIDEMIOLOGY AND PATHOBIOLOGY

E. granulosus species occur on all continents and in circumpolar, temperate, subtropical, and tropical zones. The highest prevalence of the parasite is found in parts of Eurasia, Africa,[15] Australia, and South America. Within the endemic zones, the prevalence of the parasites varies from sporadic to high, but only a few countries can be regarded as being free of *E. granulosus*.

It is difficult to determine the true incidence of cystic echinococcosis because of the slow rate of growth and variable clinical presentation. However, mass community-based surveys using portable ultrasound scanners suggest infection rates of up to 6.6% in endemic areas.[16] The great majority of *E. granulosus* isolates from human patients thus far have been of the sheep genotype (G1).

Echinococcal cysts consist of a periparasitic host tissue (pericyst or adventitia), which encompasses the larval endocyst, and the endocyst itself. The endocyst has an outer, acellular laminated layer and an inner, or germinative, layer that gives rise to brood capsules and protoscolices. The cyst is filled with clear fluid, numerous brood capsules, and protoscolices. Some cysts may also harbor daughter cysts of variable size. The protoscolices convert to tapeworms in the canine definitive hosts but can also form new cysts when released in mammalian tissues.

CLINICAL MANIFESTATIONS

The presentation of human cystic echinococcosis is protean.[17,18] Patients may seek medical attention when a large cyst has a mechanical effect on an adjacent organ or rupture of a cyst causes an acute hypersensitivity reaction. However, the cyst is often diagnosed incidentally during ultrasound examination, chest radiography, or body scanning performed for other clinical reasons. The liver, which is the most frequent location of echinococcal cysts, represents approximately 70% of cases (Chapter 137).[19] The lungs are the second most common location. However, cystic echinococcosis can occasionally occur in virtually any other organ.

Common symptoms are upper abdominal discomfort and pain, poor appetite, and a mass in the abdomen. Physical findings are hepatomegaly, a palpable mass on the surface of the liver or other organs, and abdominal distention. Other manifestations include jaundice, colic-like pains, portal hypertension, ascites, and compression of the inferior vena cava. If cysts in the lung rupture into the bronchi, symptoms may include intense cough, a salty taste in the mouth, or vomiting of hydatid material and cystic membranes. Patients may present with a chest mass, chest pain, chronic cough, pneumothorax, eosinophilic pneumonitis, pleural effusion, parasitic lung embolism, hemoptysis, or biliptysis. Cysts in the heart can cause a cardiac mass, pericardial effusion, and embolism. Cysts in the breast must be differentiated from neoplasms. Cysts located in the spine and in the brain can cause serious neurologic symptoms, including paralysis and seizures.

DIAGNOSIS

The diagnosis of cystic echinococcosis is based on imaging methods and on serology, but serology has only a confirmatory role. Routine laboratory tests are nonspecific. Cyst rupture into the biliary tree may cause elevation of the alkaline phosphatase level, sometimes in association with hyperamylasemia and eosinophilia (up to 60%). Unless the cyst has ruptured, eosinophilia is low grade or absent.

Imaging

Modern imaging tools (ultrasound, CT, and, to a lesser extent, MRI) are central to the diagnosis and clinical management of cystic echinococcosis. Ultrasound is the procedure of choice to diagnose asymptomatic cystic echinococcosis.[20] Ultrasound is also useful for longitudinal studies, such as monitoring the response of cysts to treatment and recording cyst growth rate, with a classification system that defines six cyst stages that are assigned to three clinical groups (Fig. 325-2). The active group comprises developing cysts, which may be unilocular (CE1) or multivesicular with daughter cysts (class CE2), and are usually found to be viable. The transitional group (class CE3), which contains cysts that are usually starting to degenerate, includes the "water lily sign" for floating membranes (subclass CE3a) and predominantly solid cysts with daughter cysts (subclass CE3b). The inactive group (classes CE4 and CE5), which exhibits involution and signs of solidification of cystic contents with increasing degrees of calcification, is nearly always found to be nonviable.

CT scanning has the advantage of inspecting any organ, detecting smaller cysts located outside the liver, locating cysts precisely, and sometimes differentiating parasitic from nonparasitic cysts. MRI may have some advantages over CT scanning in the evaluation of postsurgical residual lesions, recurrences, and selected extrahepatic infections, such as cardiac infections. Furthermore, MRI reproduces the ultrasound-defined features of cystic echinococcosis better than CT does. If ultrasound cannot be performed because of a cyst's location or because of patient-specific reasons, MRI with heavily T2-weighted series is preferable to CT. Plain radiographs are used for cysts in the lungs, bone, and muscle, as well as to detect calcified cysts.

Serology

Serologic tests are useful for confirmation of presumptive imaging diagnoses, but their sensitivity varies with the location of the cysts. Hepatic cysts are more likely to elicit an immune response than are pulmonary, brain, or splenic cysts. Serologic test results are usually positive when the endocyst is detached (CE3a) or in an active (CE1, CE2) or transitional (CE3b) stages. Serologic test results are generally negative in patients with inactive cysts (CE4 and CE5). Titers tend to decrease slowly as a cyst becomes inactive (CE4, CE5) and after radical surgery. Titers may remain positive after conservative surgery in which the antigen source (the germinal layer) is not completely removed. Antibody titers usually increase immediately after medical or percutaneous treatments because of the mobilization of the antigen following disruption of the cyst's integrity.

Other Diagnostic Procedures

Polymerase chain reaction (PCR) testing of biopsy specimens can provide rapid and accurate diagnosis.[21] Transhepatic fine-needle aspiration of the cyst under ultrasonographic guidance and anthelmintic coverage with albendazole (typically 10 to 15 mg/kg/day in two daily doses) is useful to differentiate cystic echinococcosis, malignant neoplasms, abscesses, and nonparasitic cysts. The procedure must be carried out in the presence of an anesthesiologist ready to manage the rare but possible anaphylactic reaction.

TREATMENT

The appropriate treatment depends on factors of the individual patient, the characteristics of the cyst, the therapeutic resources available, and the physician's preference. Medical treatment, percutaneous procedures, and a "watch and wait" approach have replaced surgery as the treatment of choice in selected cases.[22]

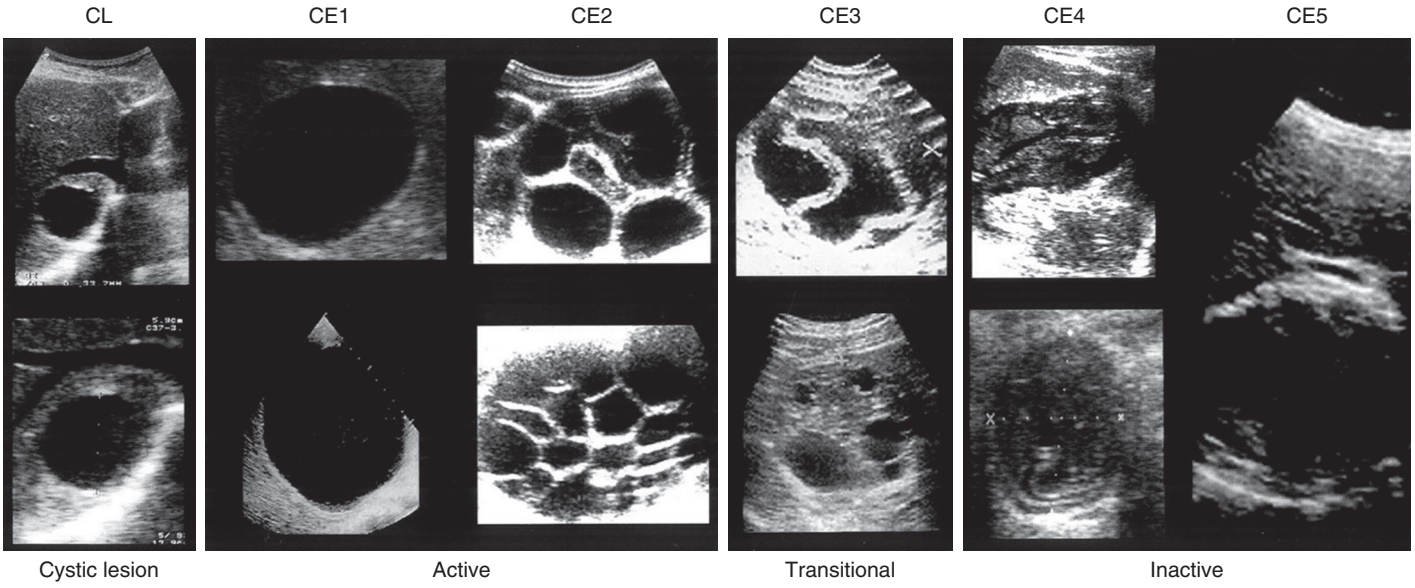

FIGURE 325-2. World Health Organization Informal Working Group on Echinococcosis standardized ultrasound classification of cystic echinococcosis. CL lesions are cystic lesions lacking a distinct wall and may have other diagnoses. CE1 lesions are cystic lesions with a visible wall that may demonstrate protoscolices ("hydatid sand"). CE2 lesions include internal septation. CE3 lesions may be detached from the wall (CE3a, *top row*) or have daughter cysts with internal thickening (CE3b, *bottom row*). CE4 lesions are heterogeneous lesions with degeneration. CE5 lesions show thick calcification.

Watch and Wait

Inactive liver cysts (CE4 and CE5) that are free of complications, such as compression on neighboring organs, are increasingly monitored without being treated.

Chemotherapy for CE1 and CE3a Cysts

Albendazole (Chapter 315), which is the antiparasitic drug of choice for cystic echinococcosis, is administered orally at a dosage of 10 to 15 mg/kg/day; administration should be continuous without treatment interruptions for at least 30 days and continued until resolution.[23] Albendazole induces solidification in small and medium-sized CE1 and CE3a cysts, whereas it has generally little effect on giant (diameter >10 cm) CE1 and CE3a cysts and is ineffective when used alone on CE2 and CE3b cysts.

Adverse effects of benzimidazoles (Chapter 315) include hepatotoxicity, leukopenia, thrombocytopenia, and alopecia. Increases in aminotransferase levels may be due to drug-related efficacy or real drug-related toxicity. Whereas teratogenic risks are theoretical, it is nonetheless good practice to avoid use during pregnancy when possible and to delay treatment until after delivery unless it is absolutely necessary.

Percutaneous Treatments for CE1 and CE3a Cysts

Percutaneous techniques either destroy the germinal layer with scolicidal agents or evacuate the entire endocyst. The most successful method aimed at destroying the germinal layer is PAIR (puncture, aspiration, injection of a scolicidal agent, and reaspiration).[A4] Many modified catheterization techniques can be used for cysts that are difficult to drain, such as multivesiculated cysts or cysts with predominantly solid content and daughter cysts. The risk of lethal anaphylaxis is 0.03%, whereas reversible allergic reactions complicate 1.7% of procedures. Prophylactic administration of albendazole (10 to 15 mg/kg/day) for at least 30 days after puncture should always accompany PAIR. PAIR is generally successful at inducing permanent solidification in CE1 and CE3a cysts, but multivesicular cysts (i.e., CE2 and CE3b) tend to relapse repeatedly after PAIR.

Surgery for Complicated Cysts and CE2 and CE3b Cysts

Surgery remains the main therapy in complicated cysts (i.e., cysts with rupture, biliary fistula, compression of vital structures, superinfection, or hemorrhage), cysts at high risk of rupture, or large cysts with many daughter vesicles that are not suitable for percutaneous treatments.[24] Surgery can be performed as an open procedure, with either radical or conservative techniques, or laparoscopically. In all hepatic cases, perioperative albendazole (10 to 15 mg/kg/day) prophylaxis, from 1 week before surgery until 4 weeks postoperatively, is recommended as a cautionary measure to minimize the risk that fluid spillage will result in secondary echinococcosis from seeding of protoscolices in the abdominal cavity. Some authorities treat with praziquantel (50 mg/kg/day or per week in divided doses) as well. Most experts recommend avoiding preoperative antiparasitic drugs for lung and intracranial disease due to increased risk of spillage.

PROGNOSIS

Follow-up is crucial to evaluate the efficacy of treatment. Long-term follow-up, generally more than 5 years, is required to evaluate local recurrences, which have been reported up to 10 years after apparently successful treatment. When the combination of imaging and serology is inconclusive, fine-needle aspiration should be performed to ascertain the viability of the cystic contents.

ALVEOLAR HYDATID DISEASE (*ECHINOCOCCUS MULTILOCULARIS*)

Alveolar hydatid disease is caused by the tissue forms of *Echinococcus multilocularis*.

EPIDEMIOLOGY AND PATHOBIOLOGY

E. multilocularis is endemic in arctic and alpine areas of the Northern Hemisphere.[25] It is highly endemic in western China, Tibet, and central Asia. *E. multilocularis* also is an important problem in alpine areas and adjacent forested areas of central Europe. Alveolar hydatid disease due to European lineage *E. multilocularis* has recently emerged in western Canada.[26]

In tissues, typically the liver, *E. multilocularis* grows as a budding mass rather than as a large cystic lesion. The tissues resemble lung tissues, hence the name "alveolar." The normal definitive hosts are canines, including wolves and foxes. The normal intermediate hosts are rodents. Humans are accidentally infected by contact with soil containing the ova.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Human *E. multilocularis* infection almost invariably involves the liver, in which it is manifested as a tumor-like mass that gradually expands during decades. The main symptoms are liver discomfort and swelling. Diagnosis is by demonstration of a characteristic mass on imaging studies (e.g. ultrasound, CT, or MRI), with the etiology confirmed by serologic tests.

TREATMENT AND PROGNOSIS

Surgery is the mainstay of treatment of *E. multilocularis*. When feasible, all infected tissues should be removed. Apparently curative therapy should be followed by a 2-year course of albendazole (10 to 15 mg/kg/day) to decrease the risk of relapse. In some cases, resection is feasible only when it is accompanied by liver transplantation. In cases that are not amenable to surgical resection, prolonged courses of albendazole continued indefinitely can suppress growth of the lesion. After treatment with benzimidazoles, mortality is similar to that of the age- and sex-matched general population.

OTHER LARVAL CESTODE INFECTIONS

Sparganosis is caused by infection with the larval (plerocercoid) stage of *Spirometra mansonoides*. Infection is acquired by ingestion or or exposure of skin to infected meat (e.g., frogs, birds, fish). After infection, plerocercoids develop in the tissues, typically presenting as subcutaneous or central nervous system nodules or occasionally larva migrans symptoms. Treatment usually involves removal of the nodule.

Coenurosis is a rare larval cestode infection caused by human infection with the larval stage of the dog tapeworms *Taenia multiceps* and *Taenia serialis*. In the tissue, the larva forms a cystic lesion that contains multiple scolices (the coenurus). The cystic lesion is usually single and most frequently identified in brain, eye, or soft tissues. Treatment usually involves removal.

Echinococcus oligarthrus and *Echinococcus vogeli* have been associated with polycystic hydatid disease in northern South America. *Taenia crassiceps* has been identified in the eye and in tissues of compromised hosts. *Hymenolepis*-like organisms have also been identified in tissues of AIDS patients.

326 TREMATODE INFECTIONS

LUIS A. MARCOS

SCHISTOSOMIASIS

DEFINITION

Schistosomiasis, which is classified as a neglected tropical disease, is a parasitic infection caused by the trematode worms (blood flukes) of the genus *Schistosoma*. It has been reported in 78 countries worldwide, with 290 million people infected and nearly 800 million at high risk for infection. Mortality from schistosomiasis is estimated at 13,000 deaths per year, and the burden of disease at 3.3 million disability-adjusted life-years lost per year.

The Pathogen

Six major species of *Schistosoma* affect humans and cause two main forms of schistosomiasis: intestinal (*S. mansoni, S. japonicum, S. intercalatum, S. mekongi,* and *S. guineensis)* and urogenital (*S. haematobium)*. Schistosomas are long, cylindrical worms. The large male (6 to 11 mm × 2 to 4 mm) has a ventral gynecophoric canal in which the female (7 to 28 mm × 1 to 2 mm) is held during copulation.

EPIDEMIOLOGY

Schistosomiasis occurs mainly in areas with poor sanitation in rural, periurban, and urban areas in endemic countries.[1] The World Health Organization has set a goal of eliminating schistosomiasis by 2030, but schistosomiasis is still endemic in 78 countries. *S. mansoni* is found in the Arabian Peninsula, Egypt, Libya, Sudan, most countries in sub-Saharan Africa, Brazil, Suriname, and Venezuela. *S. mansoni* is found in Africa, South America (Brazil, Venezuela, and Surinam), and the Caribbean. *S. haematobium* is found in Africa and the Middle East, *S. japonicum* in China and the Philippines, *S. intercalatum* in West and Central Africa, *S. mekongi* in Southeast Asia, and *S. guineensis* in Cameroon, Equatorial Guinea, Gabon, and Sao Tomé.

The endemicity of schistosomiasis depends on the urban disposal of urine *(S. haematobium)* and feces *(S. mansoni, S. japonicum, S. intercalatum, S. mekongi, S. guineensis),* the presence of suitable snail hosts, and human exposure to cercariae. The freshwater snail intermediate hosts are *Biomphalaria* species in Africa and *Biomphalaria glabrata (Australorbis)* and *Tropicarbis* in South America and the West Indies. In some cases, the endemicity of schistosomiasis may be maintained by animal reservoirs. Such is the case with *S. japonicum,* which infects dogs and cows.[2]

Etiology and Life Cycle

Adult worms live in the mesenteric veins (*S. mansoni, S. japonicum, S. mekongi, S. intercalatum,* and *S. guineensis*) or in the venous plexus around the lower ends of the ureters and the urinary bladder (*S. haematobium*) (Fig. 326-1). In these sites, they start their sexual reproduction by releasing eggs. Once deposited in the host, eggs may stay in the mesenteric vein, be trapped in the intestines, escape to the intestinal lumen, and migrate by portal blood to the liver (*S. mansoni, S. japonicum;* Fig. 326-2). Eggs of *S. haematobium,* which

FIGURE 326-2. Egg of *S. mansoni* (120 µm long × 50 µm wide).

ABSTRACT

The main trematode infections comprise of *Schistosoma spp*, liver flukes (*Clonorchis sinensis, Fasciola gigantica , Fasciola hepatica , Opisthorchis felineus ,* and *Opisthorchis viverrini*), lung flukes (*Paragonimus* spp), and intestinal flukes (e.g., *Echinostoma* spp, *Fasciolopsis buski,* and the heterophyids). *Clonorchis, Opisthorchis, Fasciola,* and *Paragonimus* are foodborne trematodes, whereas *Schistosoma* is transmitted by contact with contaminated water. More than 1.5 billion people are at risk for these infections. Each infection has a specific geographic distribution and affects certain organs. Management and treatment depend on the species. Trematode infections are a major public health concern, with enormous worldwide economic impact.

may be trapped in the intestines and bladder, may escape to the intestinal or bladder lumen. After being excreted with feces or urine into fresh water, the eggs hatch and release ciliated motile miracidia that penetrate into snails, which are the intermediate hosts. Following asexual multiplication in the snail, the development of cercariae, which are the infective forms for humans, requires 4 to 7 weeks. After leaving the snails, the cercariae can survive in fresh water for almost 72 hours. When penetration of the skin in the human host occurs, the cercariae lose their tails and change into schistosomula. Schistosomula migrate to the lungs and, in about 6 weeks, mature to adult worms that descend to their final habitat. Viable eggs can be seen in excretions (i.e., stool or urine) 5 to 9 weeks after cercarial penetration. The lifespan of the worms ranges from 5 to 10 years.

PATHOBIOLOGY

Four main pathophysiologic mechanisms have been proposed in acute human schistosomiasis infection: a serum sickness-like hypersensitivity reaction (Chapter 230), which is triggered by the deposition of eggs; a systemic hypersensitivity reaction against the migrating schistosomula and eggs; a toxemic and allergic reaction to the migrating and maturing larvae of *Schistosoma,* but not to eggs; and a more generalized systemic, immunologically mediated, Loeffler-like reaction, not specifically related either to larvae or to adult worms or to eggs.

In chronic schistosomiasis, tissue injury is mediated by egg-induced granulomas and the subsequent appearance of fibrosis. In *S. haematobium,* infected eggs induce the formation of granuloma in the urinary tract. Because the habitat of *S. mansoni, S. japonicum, S. mekongi, S. guineensis,* and *S. intercalatum* worms is the mesenteric blood vessels, the intestines are involved primarily, and egg embolism results in secondary involvement of the liver. Host genetics, immunologic response, and parasite load measured by egg count in the stool are associated with a greater chance for hepatosplenic involvement. Interleukin (IL)-4, IL-13, and IL-17 have been associated with granuloma formation and liver fibrosis. Enzymes and antigens released from eggs sensitize host lymphocytes, which migrate to areas of egg deposition and recruit other cell types, such as macrophages, eosinophils, and fibroblasts. The size of these granulomas and the resulting fibrosis lead to most of the characteristic chronic fibro-obstructive lesions in schistosomiasis. In the liver, the granulomas result in perisinusoidal obstruction of portal blood flow, portal hypertension, splenomegaly, esophageal varices, and portosystemic collateral circulation. Liver cell perfusion is not reduced; consequently, liver function test results remain normal for a long time.

In schistosome-infected populations, the intensity of infection increases during the first two decades of life as children accumulate worms, and then declines. Although exposure decreases with age, the lower intensities of infection in older individuals are due in part to acquired resistance. In the *S. haematobium*–infected population, immunoglobulin (Ig) E increases progressively with age, and IgE antibodies directed against adult worm antigens are associated with subsequent low intensities of reinfection. Similar associations between high IgE levels or a high IgE/IgG4 ratio and resistance to reinfection have been found among Brazilian and Kenyan subjects exposed to *S. mansoni*. In contrast, susceptibility to reinfection has been associated with IgG4, which may serve as blocking antibody that inhibits the action of IgE. A major codominant gene, called *SM1,* in the human host's genome controls the intensity of infection by *S. mansoni*.

Modulation of the immune response is a characteristic of chronic schistosomiasis, and *S. mansoni* antigens downmodulate the immune response by increasing their production of regulatory cytokines such as IL-10 and the frequency of regulatory T cells. *S. mansoni* infection attenuates the clinical manifestations of type 1 diabetes and experimental autoimmune encephalitis in mice. In humans, *S. mansoni* attenuates the clinical manifestations of asthma and is inversely associated with the development of myelopathy related to human T-cell leukemia virus type 1 (HTLV-1) infection (Chapter 360). *S. mansoni* infection may impair immunologic response to vaccines and change manifestations of other infectious diseases.

CLINICAL MANIFESTATIONS

Clinical manifestations of schistosomiasis are divided into schistosome dermatitis, acute schistosomiasis, and chronic schistosomiasis. Schistosome dermatitis, or swimmer's itch, is seen mainly when avian cercariae penetrate the skin and are destroyed. Schistosome dermatitis is a sensitization phenomenon that occurs in previously exposed persons. The cercariae evoke an acute inflammatory response with edema, early infiltration of neutrophils and lymphocytes, and later invasion of eosinophils. A pruritic papular rash occurs within 24 hours after the penetration of cercariae and reaches maximal intensity in 2 to 3 days.[3]

Acute schistosomiasis occurs usually 20 to 50 days after primary exposure. Though asymptomatic in endemic areas, acute schistosomiasis is becoming a frequent and major clinical problem when nonimmune individuals from urban regions are exposed for the first time to a heavy infection in an endemic area. The clinical syndrome (i.e., fever, chills, liver and spleen enlargement, and marked eosinophilia) originally described for *S. japonicum* infection, and still common for this species, is increasingly being diagnosed in Brazil and Africa in individuals with *S. mansoni* infection. Malaise, diarrhea, weight loss, cough, dyspnea, chest pain, restrictive respiratory insufficiency, and pericarditis are also documented in this phase. Acute disease is not observed in individuals who live in endemic areas for schistosomiasis.

S. mansoni and *S. japonicum*

In chronic schistosomiasis, intestinal involvement commonly manifests with abdominal pain, irregular bowel movements, and blood in the stool. Hepatosplenic involvement is the most important cause of morbidity with *S. mansoni* and *S. japonicum*.[4] Patients may remain asymptomatic until the manifestation of hepatic fibrosis and portal hypertension develops. Bleeding esophageal or gastric varices may cause hematemesis. Anemia and decreasing levels of serum albumin are observed. Some patients develop severe hepatosplenic disease, with jaundice, ascites, and hepatic failure.

Concomitant infection by *Salmonella* species (Chapter 284) and, to a lesser extent, other gram-negative bacteria with *S. mansoni* or *S. haematobium* leads to a picture of prolonged fever, hepatosplenomegaly, and mild leukocytosis with eosinophilia. Coinfection with *S. mansoni* and hepatitis B or C virus (Chapters 134 and 135) exacerbates liver pathology.

Glomerulonephritis (Chapter 107) and hypersplenism (Chapter 154) are other complications associated with hepatosplenic schistosomiasis. Pulmonary hypertension (Chapter 69),[5] which is increasingly recognized with the use of more advanced diagnostic technology, is detected in about 10% of patients with liver fibrosis. In countries endemic for *S. mansoni,* up to 30% of all cases of pulmonary hypertension are due to schistosomiasis.

Cerebral schistosomiasis, which is observed in patients with *S. japonicum* infection, may occur as early as 6 weeks after infection, and its most common manifestation is focal seizures. Signs and symptoms of generalized encephalitis may occur. In *S. mansoni* infection, neurologic involvement is mainly characterized by transverse myelitis.

An association between *S. mansoni* or *S. haematobium* and human immunodeficiency virus (HIV) infection has been documented in areas where both infections are present. Although the immune response of patients with schistosomiasis is altered by HIV, it has not been reported to be associated with any clear changes in the degree of infection or severity of manifestations of schistosomiasis.

S. haematobium

In *S. haematobium* infection, the main organ system involved is the urinary tract.[6] The acute granulomatous response to parasite eggs in the early stages causes urinary tract disease, such as urethral ulceration and bladder polyposis. In chronic disease, usually in older patients, granulomas at the lower ends of the ureters obstruct urinary flow and may cause hydroureter and hydronephrosis. Bladder fibrosis and calcification are also seen in this phase. Up to 70% of infected individuals have hematuria, dysuria, or urinary frequency. Radiologic findings include hydronephrosis, hydroureter, ureteral strictures, dilation or distortion, ureteral calcifications, ureterolithiasis, calcified bladder, polyps, reduction in bladder capacity, irregular contraction of the bladder wall, or a dilated bladder because of bladder neck fibrosis. An increased incidence of squamous cell urothelial carcinoma of the bladder (Chapter 182) is seen in endemic areas of *S. haematobium* infection. Female genital schistosomiasis can lead to infertility and a higher risk of HIV transmission. *S. haematobium* eggs have occasionally been found in the lungs, with subsequent focal pulmonary arteritis and pulmonary hypertension.

DIAGNOSIS

Epidemiologic risk factors such as a history of contact with contaminated water and appropriate clinical manifestations are key to raise suspicion of schistosomiasis. About 50% of infected patients have eosinophilia. Liver enzymes and

TABLE 326-1 DIAGNOSIS OF SCHISTOSOMIASIS

SCHISTOSOME	EGGS	DIAGNOSIS
S. haematobium	Mainly found in urine but may be found in stools or rectal biopsy specimens Eggs: 143 × 50 µm; spindle shaped: rounded anterior, conical posterior, tapering to a terminal delicate spine	PCR in serum: 90% of patients in acute infection are positive Obtain urine sample at midday (when eggs are excreted); more than one sample may be needed PCR in urine is more sensitive than microscopy and is highly specific Examine urine directly or by filtering 10 mL of urine through a nucleopore membrane Urine-circulating antigen test for diagnosis of light infection and serologic test to diagnose early or light infection Rectal biopsy in suspected cases with negative urine for egg and for circulating cathodic antigen
S. mansoni	Found in stool eggs: 155 × 66 µm; oval with lateral, long spine	PCR in serum: 90% of patients in acute infection are positive Examine stool for eggs PCR of stool is more sensitive than microscopy and is highly specific Use the Kato-Katz thick smear method for quantification purposes Urine-circulating cathodic antigen test, serologic testing, or rectal biopsy to diagnose stool-negative cases, particularly in lightly infected patients
S. japonicum	Found in stool Eggs: 89 × 67 µm; oval or rounded with a lateral, short, sometimes curved spine	Examine stool for eggs Kato-Katz thick smear (for quantitative assessment) Urine-circulating cathodic antigen test, serologic test or rectal biopsy for those with light infections, especially with less common manifestations (e.g., cerebral schistosomiasis) Nested PCR is promising for diagnosis in endemic areas
S. mekongi	Found in stool Eggs: 60 × 32 µm; smaller than eggs of *S. japonicum*	Examine stool for eggs
S. intercalatum	Found in stool Eggs: 180 × 65 µm; terminal spine	Examine stool for eggs

PCR = polymerase chain reaction.

the serum bilirubin level are usually normal or mildly elevated. Anemia and thrombocytopenia may occur in severe chronic schistosomiasis. Hematuria is common in *S. haematobium*.

Molecular techniques to detect schistosoma DNA in stool, urine, and blood specimens have a high sensitivity for diagnosing acute infection and are very useful in returning travelers and in individuals who may have light infection.[7] Quantification of circulating cathodic antigen (CCA) in urine also has a high sensitivity and can monitor the efficacy of antischistosome chemotherapy. A significant decrease in antigen levels is observed as early as 10 days after therapy. Serologic assays can detect antibodies to *S. mansoni* antigens but cannot distinguish between active and past exposure. As a result, they can be very useful for diagnostic purposes in travelers with suspected acute infection[8] but not for residents in endemic areas.

Despite the appeal of these molecular and immunologic tests, examination of the stool for eggs is an essential part of the evaluation, and a definitive diagnosis still often requires finding schistosome eggs in stool, urine, or a biopsy specimen, usually from the rectum (Table 326-1).[9,10] Because schistosome eggs may be few, concentration by sedimentation should be performed. All eggs from stools, urine, or tissues should be examined under high power to determine their viability by visualizing the activity of cilia of the excretory flame cells of the enclosed miracidium. Dead eggs may persist for a long time after successful therapy or natural death of the worms. The presence of only dead eggs does not necessarily require treatment. Because the intensity of infection is associated with morbidity, quantitative techniques are recommended. For *S. mansoni* and *S. japonicum*, the Kato-Katz thick smear method is used. In patients with chronic *S. mansoni* and *S. japonicum* infection and liver disease, the diagnosis is sometimes made by documentation of eggs in liver specimens. Ultrasonography allows determination of the degree of liver fibrosis. *S. mekongi* and *S. intercalatum* infections are diagnosed by examining the stool for eggs.

Urine examination for *S. haematobium* eggs can be performed by direct or concentration methods. Samples should be obtained at midday, when excretion of eggs is maximal. Assessment of urinary tract pathology by ultrasonography is recommended after the diagnosis is confirmed because of the increased incidence of carcinoma of the bladder (Chapter 182).

TREATMENT

Praziquantel, which is a pyrazinoisoquinoline derivative, is the drug of choice for the treatment of schistosomiasis. The standard recommended treatment is a single dose of praziquantel, 40 mg/kg, for *S. mansoni, S. haematobium*, and *S. intercalatum* infection. In *S. japonicum* infection, a total dose of 60 mg/kg is recommended, split into two or three doses in a single day. For *S. haematobium*, overall cure rates are similar with single-dose (40 mg/kg) and double-treatment (40 mg/kg with 2-week interval) praziquantel, but double treatment significantly reduces the intensity of infection and microhematuria, so it may reduce morbidity. *S. mekongi* may require two treatments at 60 mg/kg body weight.

Oxamniquine (40 mg/kg) is also effective as an alternative to praziquantel. Combination therapies, such as single-dose praziquantel plus dihydroartemisinin piperaquine (40 mg/320 mg), may be even more efficacious for the treatment of intestinal schistosomiasis.[A1]

The most common adverse events observed with praziquantel or oxamniquine are related to the gastrointestinal tract: abdominal pain or discomfort, nausea, vomiting, anorexia, and diarrhea. These symptoms can be observed in up to 50% of patients but are usually well tolerated.

PREVENTION

Mass drug administration with praziquantel[11] has been used as the mainstay of programs for the control and prevention of schistosomiasis morbidity,[A2] with school-based programs showing the most promising results.[A3,A4] However, this approach alone is not sufficient to eliminate or interrupt transmission of this disease. The development of anti-*Schistosoma* vaccines is necessary. Additional measures such as provision of clean water, use of molluscicides, adequate sanitation, and improvement of socioeconomic conditions also should be implemented to control the disease.[12]

PROGNOSIS

With the recommended dosages of praziquantel, recorded cure rates are 75 to 85% for *S. haematobium*, 63 to 85% for *S. mansoni*, 80 to 90% for *S. japonicum*, 89% for *S. intercalatum*, and 60 to 80% for double infections with *S. mansoni* and *S. haematobium*.[13] A decrease in the efficacy of praziquantel has been observed in patients coinfected with HTLV-1 (Chapter 360). High-risk groups for the development of liver fibrosis despite treatment include men, older individuals, and fishermen.[14]

LIVER, INTESTINAL, AND LUNG FLUKES

LIVER FLUKES

The geographic distribution, clinical manifestations, diagnosis, and treatment of liver, intestinal, and lung fluke infections are summarized in Table 326-2.[15]

FASCIOLIASIS

Fascioliasis is a zoonosis caused by *Fasciola hepatica* (adult: 30 × 13 mm) or *F. gigantica* (adult: 75 × 20 mm). The most common natural hosts are cattle, sheep, and goats.

TABLE 326-2 CLINICAL MANIFESTATIONS, DIAGNOSIS, AND TREATMENT OF LIVER, INTESTINAL, AND LUNG FLUKE INFECTIONS IN HUMANS

FLUKE, NUMBER OF PEOPLE INFECTED, AND GEOGRAPHIC DISTRIBUTION	CLINICAL MANIFESTATIONS OF ACUTE AND CHRONIC PHASES	DIAGNOSIS*	TREATMENT†
LIVER FLUKES			
Fasciola spp 17 million Cosmopolitan	Acute ‡Hepatomegaly, eosinophilia, fever, abdominal pain, metastatic-like lesions on liver CT Chronic §Biliary obstruction, gallstones, fibrosis, cholangitis	Stools are negative Serology (Fas2 ELISA) Eggs in stool Fas2 ELISA	TCZ
Opisthorchis spp 11.2 million Asia	‡Fever, malaise, arthralgia, lymphadenopathy, and rash §Jaundice, cholangitis, cholangiocarcinoma	Serology Eggs in stool	PZQ
Clonorchis spp 35 million Asia, Eastern Europe	‡Fever, rash, malaise, and RUQ abdominal discomfort §Choledocholithiasis, cholangitis, cholecystitis, liver abscess, and possible cholangiocarcinoma	Serology Eggs in stool	PZQ
INTESTINAL FLUKES			
Fasciolopsis buski and others¶ 50 million Asia and North Africa	Small bowel inflammation, ulceration, mucus secretion, protein-losing enteropathy, malabsorption	Eggs in stool	PZQ
LUNG FLUKE			
Paragonimus spp 23 million Asia, Americas, Africa	‡Abdominal pain, pleuritic pain, cough, eosinophilia §Hemoptysis, cough, chronic pleural effusions, pulmonary cysts	Abscess serology Eggs in sputum or stool	PZQ or TCZ

*For egg morphology and size, refer to text in the Diagnosis section.
†For drug regimens, refer to text in the Treatment section.
‡Acute.
§Chronic. For chronic infection, a sedimentation technique is preferred (suggested technique: rapid sedimentation technique or Kato-Katz technique).
¶Diagnosis and treatment also apply for other intestinal flukes.
CT = computed tomography; ELISA = enzyme-linked immunosorbent assay; PZQ = praziquantel; RUQ = right upper quadrant; spp = species; TCZ = triclabendazole.

EPIDEMIOLOGY

The infection is distributed globally. An estimated 2.6 million people are infected by this parasite, mainly in South America, Africa, and Asia. The highest prevalence rates (>60%) have been reported in Peru and Bolivia.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

The life cycle begins when the parasite's eggs in stool are deposited in water; miracidia appear, develop, and hatch in 9 to 14 days and invade many species of freshwater snails (*Lymnaea* spp), in which they multiply as sporozoites, rediae, and cercariae during a period of 4 to 7 weeks. The parasite then leaves as free-swimming cercaria that subsequently attach to watercress, water lettuce, alfalfa, mint, parsley, or khat. The main source of infection is consumption of raw vegetables or water contaminated with metacercariae. Women have a higher incidence of the disease, with more severe infections and complications than seen in men.

After consumption of contaminated vegetables, the larvae excyst in the duodenum and then migrate through the bowel wall to the liver through the peritoneal cavity. In 4 weeks they reach the liver, penetrate the capsule, and cause inflammation and pain. Acute diarrhea of 2 to 5 days' duration may occur before liver invasion. During their migration through the liver, the ongoing inflammatory process is accompanied by fever, pain, and eosinophilia. In a few cases, intense hemorrhage may manifest as a subcapsular liver hematoma. Computed tomography (CT), magnetic resonance imaging, or ultrasonography can detect these initial lesions. Migration of the parasite leaves a track that can be observed in histologic sections or by imaging (CT). The flukes sometimes die and leave cavities filled with necrotic debris, which is eventually replaced by scar tissue that becomes calcified. After 3 to 5 months of migration in the liver, the juvenile larvae reach the bile ducts.

During this invasive, migratory, or acute phase the clinical manifestations are prolonged fever, hepatomegaly, abdominal pain, and eosinophilia. Multiple hypodense lesions are seen on CT, similar to metastases, but they change in position, attenuation, and shape in time because the parasites are still migrating. Acute fascioliasis is clinically similar to acute cholecystitis (Chapter 141) but with the addition of significant eosinophilia. Hyperbilirubinemia is notably absent in this phase. Other manifestations are anorexia, weight loss, nausea, vomiting, cough, diarrhea, urticaria, lymphadenopathy, and arthralgias. Occasionally, the juvenile larvae reach other ectopic or extrahepatic locations, such as subcutaneous tissue, the pancreas, eye, brain, and stomach wall. In endemic areas, the acute phase manifestations can be superimposed on chronic infection.

Arrival of the parasite in the bile ducts marks the beginning of the chronic phase. Mature flukes consume hepatocytes and duct epithelium and reside for years in the hepatic and common bile ducts and sometimes in the gallbladder. In this chronic phase, the liver contains large dilated, thick-walled, and calcareous bile ducts with yellowish-brown bile. The bile ducts have a thickened hyperplastic wall with marked fibrosis. Symptoms usually reflect biliary obstruction with colicky pain in the right upper quadrant and epigastric area. Eosinophilia is absent in half of the chronic cases. Bacterial superinfection of these cysts and consequent cholangitis can develop. Other complications are hemobilia, liver abscess,[16] and liver fibrosis. The serum alkaline phosphatase level is commonly elevated because of biliary obstruction, which sometimes requires surgical intervention. On imaging, the initial lesions often may be confused with hepatic metastases. Other findings on CT are hepatomegaly, tracklike hypodense lesions in subcapsular locations, multiple hypodense nodular areas (abscess-like lesions), or low-density, serpiginous, tortuous, tunnel-like branching lesions ranging from 2 to 10 mm. CT also can show subcapsular hematoma, enhancement of the Glisson capsule, necrotic granuloma, and cystic calcifications.

After maturation, the adult flukes start laying eggs, which are passed from the sphincter of Oddi to the intestines and evacuated to the environment along with stool. Adult parasites can live in the bile ducts for up to 13 years, where they can cause biliary obstruction, with adult parasites visible on endoscopic retrograde cholangiopancreatography (ERCP).

CLONORCHIASIS AND OPISTHORCHIASIS

Clonorchiasis is caused by *Clonorchis sinensis*, also called the Chinese or oriental liver fluke (adult: 10 to 25 mm × 3 to 5 mm). Opisthorchiasis is caused by *Opisthorchis viverrini* (adult: 5 to 10 mm × 1 to 2 mm) and *Opisthorchis felineus* (adult: 7 to 12 mm × 2 to 3 mm). The most common natural hosts are dogs, cats, pigs, and some small wild mammals.

EPIDEMIOLOGY

The global estimate for the number of people infected with both infections is 46.2 million, 35 million for *C. sinensis* (15 million in China), 10 million for *O. viverrini* (8 million in Thailand and 2 million in Laos), and 1.2 for *O. felineus*. About 600 million and 80 million people are at risk of infection with *Clonorchis* and *Opisthorchis,* respectively. Both infections are endemic in the Far East, Southeast Asia, and Eastern Europe. *C. sinensis* is endemic in northeast China, southern Korea, Japan, Taiwan, northern Vietnam, and the far eastern part of Russia, whereas *O. viverrini* is endemic in Laos, Thailand, Vietnam, and Cambodia. *O. felineus* infection is prevalent in Russia, Ukraine, and Kazakhstan.

PATHOBIOLOGY

The life cycle starts when the adult worm deposits fully developed eggs, which are then passed to the environment through feces. Eggs hatch in water, and the miracidia infect their first intermediate host, which is a freshwater snail (*Bithynia* spp or *Parafossarulus* spp), where they transform into sporocysts, rediae, and cercariae. Cercariae are released from the snail and then penetrate freshwater fish, which are the second intermediate host (*Cyclocheilichthys* spp, *Puntius* spp, *Hampala dispar*); the cercariae encyst as metacercariae in the muscles or under the scales. In general, the infection is acquired by eating raw or uncooked cyprinoid fish products in rural areas or dishes such as *koi-pla,* which is a salad made with raw fish. The metacercariae pass through the stomach and reach the small intestine unharmed. Then, through the ampulla of Vater, they reach the bile ducts, where they mature into adult worms within 4 weeks and deposit yellow, operculated eggs. The parasites may live for up to 45 years in a human host.

The pathologic and clinical consequences of these flukes are related to the intensity and duration of cumulative infestations. In general, they cause inflammation around the biliary tree, severe hyperplasia of epithelial cells, metaplasia of mucin-producing cells in the mucosa, and progressive periductal fibrosis. There are clear associations between *O. viverrini* infection and cholangiocarcinoma. Several *N*-nitroso compounds and their precursors occur at low levels in fermented food, such as preserved mud fish paste *(plara),* a condiment that is a ubiquitous component of the cuisine of northeastern Thailand and Laos. Even after treatment, the advanced periductal fibrosis that may predispose to cholangiocarcinoma may persist in one third of the patients.[17]

CLINICAL MANIFESTATIONS

Acute clonorchiasis infection caused by *C. sinensis* is usually asymptomatic, but some patients may have fever, rash, malaise, and right upper quadrant abdominal discomfort. Chronic infections may be manifested as recurrent pyogenic cholangitis, cholecystitis, obstructive jaundice, hepatomegaly, cholecystitis, multiple hepatic tumors, cholelithiasis, or pancreatitis.[18] In chronic carriers with a high load of parasites, cholangiocarcinoma may develop, especially in Thailand.

Acute opisthorchiasis infection caused by *O. viverrini* can cause right upper quadrant abdominal pain, flatulence, fatigue, and a hot sensation over the abdomen. In the chronic phase, mild hepatomegaly occurs, mainly in more heavily infected patients (egg counts >10,000/g). Jaundice and splenomegaly are not observed. Intrahepatic duct stones and recurrent suppurative cholangitis are common. Whenever jaundice and ascending cholangitis are detected, fluke-related cholangiocarcinoma should be suspected.

In opisthorchiasis caused by *O. felineus,* infestation usually follows the consumption of raw, slightly salted, and frozen fish ("stroganina"). Acute symptoms occur 2 to 4 weeks later, including high-grade fever, nausea, vomiting, abdominal pain, malaise, arthralgias, lymphadenopathy, and rash. Peripheral eosinophilia is a common finding, especially during the initial 2 to 6 weeks of the infection, together with raised liver enzyme levels. In chronic infection, the eosinophilia is usually milder. Patients may have suppurative cholangitis and liver abscesses because of biliary obstruction. Ultrasonography or CT demonstrates the pathologic changes in the liver, including intrahepatic duct dilation and periductal changes.

INTESTINAL FLUKES

The most common human intestinal trematode is *Fasciolopsis buski* (adult: 20 to 75 mm × 8 to 20 mm), which is found mainly in the central and southeast parts of Asia. *F. buski* is a common parasite in pigs. Other intestinal flukes are *Heterophyes* (adult: 1 to 2 mm in length), *Metagonimus yokogawai* (adult: 1 to 2.5 mm × 0.4 to 0.75 mm), and *Echinostoma* spp (adult: 6.5 × 1 to 2 mm).

EPIDEMIOLOGY

More than 50 species of intestinal trematodes from the Far East, Middle East, and North Africa have been reported to cause human infection. *H. heterophyes* also can be found in the Nile delta region of Egypt. An estimated 40 to 50 million people are infected with one or several species of intestinal flukes. Their life cycles are similar. The adult worm attaches to the intestinal wall of humans and produces eggs that are passed in feces. The eggs reach water, where miracidia develop and penetrate the first intermediate host, which is the snail. During the course of 6 to 7 weeks inside the host snails, the eggs develop into sporocysts, rediae, and cercariae. The cercariae leave the snails to encyst in the second intermediate host, which can be freshwater snails, fish, tadpoles, or vegetables. Humans are infected by the ingestion of raw stems, leaves (especially bamboo shoots), watercress, or water chestnuts with encysted metacercariae. In the human duodenum, the metacercariae attach to the walls and become adult worms in approximately 3 months.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Although the majority of intestinal fluke infections are asymptomatic, they may cause inflammation, ulceration, and mucus secretion at the site of attachment, particularly in the duodenum and jejunum. Gastrointestinal hemorrhage, perforation, and abscesses have been observed. The differential diagnoses include typhoid fever (Chapter 284), intestinal tuberculosis (Chapter 299), and amebiasis (Chapter 323). In these endemic cases, ulcerative colitis and other inflammatory diseases of the bowel are uncommon. In heavy infection, intestinal obstruction, protein-losing enteropathy, malabsorption, impaired vitamin B_{12} absorption, hypoalbuminemia, and anasarca can occur.[19] The adult worm causes traumatic, toxic, and obstructive damage to the intestinal mucosa. Some cases have been diagnosed by direct visualization of the adult parasite via esophagogastroduodenoscopy.

PULMONARY FLUKES

Paragonimiasis is a zoonosis caused by *Paragonimus* species (adult size: 10 × 5 mm). Reservoir hosts include felids, canids, viverrids, mustelids, some rodents, and pigs. At least 10 species of *Paragonimus* are known to cause human disease; of these, *Paragonimus westermani* is the most common.

EPIDEMIOLOGY

An estimated 25 or so million people are infected worldwide with *Paragonimus* species, and about 300 million are at risk. Human paragonimiasis is distributed mainly in Southeast Asia, Japan, Korea, China, and the Philippines, where *P. westermani* is the main species. In areas of low endemicity, other reported species include *Paragonimus mexicanus* in Latin America, *Paragonimus kellicotti* in North America, *Paragonimus heterotremus* in India, and *Paragonimus africanus* and *Paragonimus uterobilateralis* in West Africa.

Paragonimiasis typically results from the consumption of raw or improperly cooked crustaceans, especially crabs. Recently in the United States, some autochthonous cases have been reported in the Midwest in people who consumed raw crayfish while camping.

PATHOBIOLOGY

The life cycle starts when the eggs are excreted unembryonated in sputum, or alternatively they can be swallowed and passed in stool. In the external environment, the eggs become embryonated, and miracidia hatch. Eggs seek the first intermediate host, a snail (families Pleuroceridae and Thiaridae), and penetrate its soft tissues. Within the snail, asexual reproduction occurs for several weeks, with transformation into sporocysts, rediae, and cercariae. Cercariae emerge from the snail and invade the second intermediate host, which is a crustacean such as a crab or crayfish, where they encyst and become metacercariae, which is the infective stage for the mammalian host. Human infection occurs by eating inadequately cooked or pickled crab or crayfish that harbor metacercariae of the parasite. The metacercariae excyst in the duodenum, penetrate the intestinal wall, and migrate through the peritoneal cavity toward the lungs.

CLINICAL MANIFESTATIONS

Most infected individuals are asymptomatic and have subclinical disease. During the first month of infection, abdominal pain may represent the juvenile larvae migrating through the abdominal cavity before reaching the lungs. Irritation of the diaphragm or pleura may cause dry cough. Fever, chest pain, fatigue, and urticaria may follow, as well as eosinophilia. Pleural effusions may be seen at this stage, with significant eosinophilia noted on analysis of pleural fluid, which can be the first clue to the diagnosis. In fact,

pleural manifestations predominate early in the disease process, whereas lesions of the pulmonary parenchyma predominate later in the course of disease. Moreover, pneumothorax and mild eosinophilia may occur only 1 month after the initiation of infection. The migrating worms may cause bronchiectasis, interstitial pneumonitis, transient hemorrhage, or bronchopneumonia. Cough and recurrent hemoptysis are common clinical findings in this phase.[20]

The chronic stage occurs when the worms are paired in a cyst in the pulmonary parenchyma. Eggs are produced 6 weeks after infection, and, if there is communication with the bronchial tree, eggs may be seen in a sputum sample under microscopy, or they can be swallowed and passed with stool. The rusty discoloration of sputum is caused by the presence of the tan- to brown-pigmented *Paragonimus* eggs; the sputa of these patients have been classically described as resembling "iron filings." Charcot-Leyden crystals can be seen.

Peripheral blood eosinophilia and elevated total serum IgE levels are observed in approximately 80% of patients. Common findings on chest CT are pleural effusion, hydropneumothorax, pulmonary nodules, consolidation of air spaces, and cysts. The most common ectopic form is cerebral paragonimiasis, which is manifested as eosinophilic meningitis or meningoencephalitis, or as residual calcifications from a past infection. Infections may persist for 20 years in humans.

APPROACH TO LIVER, INTESTINAL, AND LUNG FLUKES

DIAGNOSIS

In general, transmission of food-borne trematodiases is restricted geographically, and distribution is one of the most important factors in suspecting this diagnosis. In the appropriate clinical setting, laboratory and imaging data can add information to narrow the differential diagnosis. Acute fluke infections require a high level of suspicion.

Serologic tests, direct visualization of the migrating larvae, or empirical therapy with a significant clinical response (including reduction of eosinophilia) are major criteria to confirm the diagnosis. Since these flukes are not living in blood vessels, PCR of serum has a limited role, but it can be useful for tissue, stools, or sputum when the adult parasite releases the eggs. Under the light microscope, the morphologic characteristics and size of the eggs may be sufficient to identify the specific fluke. In the chronic phase, the diagnosis is usually made by visualization of the eggs in stool or, in the case of *Paragonimus,* in sputum. A sedimentation technique must be performed on a series of at least three stool specimens from alternate days or even weeks. Immunodiagnostics is an excellent tool, particularly for patients who do not have demonstrable eggs in clinical specimens.

Fascioliasis

If acute hepatic fascioliasis is strongly suspected, cathepsin L1–based antibody enzyme-linked immunosorbent assay (ELISA) has a sensitivity of 92% and a specificity of 84%. If negative, the diagnosis is unlikely. If serology is not available, CT of the liver can visualize the characteristic track-like lesions. However, because the parasitic lesions are very similar to metastases, liver biopsy may be necessary. If serology or CT is not available, a trial of triclabendazole with clinical (including eosinophilia) resolution is the major criterion for diagnosis.

In chronic fascioliasis, the Lumbreras rapid sedimentation and Kato-Katz techniques are the tests of choice to detect the eggs in stool. At least three stool examinations are preferred. If negative, serology can be helpful. Ultrasonography and CT have low sensitivity in this phase. ERCP usually finds the adult parasites in the bile duct when performed for other reasons and can be useful to eliminate the adult parasites causing biliary obstruction.

Opisthorchiasis

In opisthorchiasis, the Ov-CP-1–based ELISA has a sensitivity of 95% and a specificity of 96%. For *C. sinensis,* ELISA has a sensitivity between 81 and 96% and a specificity between 92.6 and 96.2%. For detection of eggs and to measure the intensity of infection, the Kato-Katz technique is preferred. Intestinal fluke eggs can be detected by performing a sedimentation stool technique, preferably in consecutive stool samples.

Paragonimiasis

For paragonimiasis, an immunoblot assay performed with a crude antigen extract of *P. westermani* is the ideal first step to confirm the diagnosis, with a sensitivity of 96% and a specificity of 99%. In the acute phase, the precise location of the migrating larva is unknown, and a biopsy may not necessarily target the parasite. When serologic findings are negative (or not available), a trial of praziquantel or triclabendazole with a positive clinical response in 48 to 72 hours is a major criterion for diagnosis.

In the chronic phase, several sputum samples must be examined by a sedimentation technique to increase sensitivity. Stool examinations are complementary because the eggs can be swallowed by the host and then passed through stool. If a pulmonary cyst contains adult parasites with eggs, but they do not have communication to the main bronchi, serologic examination is indicated to confirm the diagnosis. If not available, biopsy is warranted.

TREATMENT

For fascioliasis, 10 mg/kg of oral triclabendazole on 2 consecutive days is the treatment of choice. The cure rate is higher than 90%, but failures have been reported. Cure is achieved if stool examinations remain negative for at least 3 months. Serology usually can take more than a year to resolve. In the chronic phase, the dead parasites can occasionally cause biliary obstruction, which may require surgical intervention. For drug failure, some experts recommend multiple rounds of triclabendazole, but some infections are resistant.[21,22] For intestinal flukes (i.e., *Fasciolopsis, Heterophyes,* etc.), praziquantel, 25 mg/kg orally three times daily for 1 day, is recommended and has a cure rate 90% or greater.

For *Opisthorchis viverrini,* a single oral dose of praziquantel (40 to 50 mg/kg) has a cure rate of 91 to 97%. For clonorchiasis, the recommended treatment is praziquantel (three doses of 25 mg/kg each in 1 day, for a total dose of 75 mg/kg), which has a cure rate of 83 to 85%. For *Clonorchis sinesis,* tribendimidine is as effective as praziquantel with fewer adverse events. Tribendimidine (100 to 600 mg orally) also is an efficacious alternative to praziquantel for treating *Opisthorchis viverrine,*[A5] but may or may not be quite as efficacious.[A6]

For paragonimiasis, praziquantel (25 mg/kg orally three times daily for 3 days) or triclabendazole (10 mg/kg orally once or twice) is highly effective. For ectopic cases, surgery may be necessary. In follow-up, negative stool examinations in the ensuing weeks can confirm cure. However, because the rate of reinfection is high in individuals from endemic areas, a suddenly positive stool examination is highly suggestive of a new infection rather than failure to respond to treatment.

PREVENTION

Prevention of infection with these flukes depends on several factors, including recognizing their geographic distribution and avoiding consumption of raw vegetables, fish, crayfish, or contaminated water in endemic areas. Proper medical advice must be given to individuals traveling to or planning to reside in endemic areas, not only to prevent fluke infection but also to reduce the risk for coinfections with other parasites.

For local populations in endemic areas, the challenges are greater. Control of these flukes in animals is impractical because of wild animal reservoirs. Long-established cultural, dietary, and sanitary habits are difficult to change. However, the identification of hotspots for infection[23] can guide the administration of mass chemotherapy to highly endemic populations and may reduce the infection in humans and in selected animals.

327 NEMATODE INFECTIONS

DAVID J. DIEMERT

DEFINITION

Nematode infections are highly prevalent, affecting millions of people worldwide. Nematodes are complex, nonsegmented roundworms with specialized organs that include a protective outer coating or cuticle, a complete and functional gastrointestinal tract, and muscular, nervous, and reproductive systems. Most species are free-living in soil or water, but a few parasitize humans.

The Pathogens

Nematodes of medical importance can be categorized into those that primarily affect the gastrointestinal tract, where adult worms become established and cause disease, and those that affect other tissues and organ systems. The former includes the roundworm *Ascaris lumbricoides*, the hookworms *Ancylostoma duodenale* and *Necator americanus*, the pinworm *Enterobius vermicularis*, the whipworm *Trichuris trichiura*, and the threadworm *Strongyloides stercoralis*. Zoonotic intestinal nematodes such as *Trichostrongylus* and *Anisakis* also can incidentally infect and cause disease in humans. Nematodes that invade and cause disease primarily outside the gastrointestinal tract include those that cause lymphatic filariasis (*Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*), *Onchocerca volvulus*, *Loa loa*, and the guinea worm *Dracunculus medinensis*, as well as *Trichinella* and *Angiostrongylus* species.

Nematodes that infect humans measure from several millimeters to more than a meter in length and often survive for months to years within their host. Except for *S. stercoralis* and *Capillaria philippinensis*, adult worms cannot complete their life cycle within a human host. Instead, sexually mature adult worms mate and produce eggs or larvae that must have at least one stage of development outside the host, either in the environment or in an intermediate host.

EPIDEMIOLOGY

Nematode infections are rarely fatal; they more commonly result in chronic morbidity such as iron deficiency anemia caused by hookworm or blindness due to onchocerciasis. For most nematodes, the severity of the clinical manifestations of infection is proportional to the number of worms harbored by a given host; although light infections with only a few worms are usually asymptomatic, heavier worm burdens often cause symptoms and clinical sequelae.

Nematode infections are prevalent in the temperate and tropical regions of Africa, Asia, and Latin America. They are transmitted by the oral ingestion of embryonated eggs or by penetration of infective larvae through the skin, either by direct contact with contaminated soil or by the bite of an arthropod vector. Nematode infections are most common in areas with poor sanitation, where the environment is contaminated by human feces, and in climates that support survival of the insect vector if one is involved in the life cycle.

INTESTINAL NEMATODE INFECTIONS

ASCARIASIS

The Pathogen

A. lumbricoides, commonly known as roundworm, is acquired by oral ingestion of embryonated eggs that have been expelled in the feces of humans, who are the only host. Adult worms (Fig. 327-1) range in length between 15 and 50 cm and survive in the host for approximately 18 months.

EPIDEMIOLOGY

A. lumbricoides is the most prevalent nematode infection worldwide, affecting approximately 730 million people in sub-Saharan Africa, South and Southeast Asia, and Latin America, primarily in rural areas of high population density that lack adequate sanitation or treatment of sewage or where untreated human feces are used as fertilizer.[1] Climate is an important determinant of disease since warm temperatures and adequate moisture are needed for embryonation of eggs in soil. In endemic areas, the prevalence and intensity of infection increase significantly during the first 2 to 3 years of life, remain high between the ages of 4 and 15 years, and then decline during adulthood.

PATHOBIOLOGY

In the stomach, the egg's outer shell is dissolved by gastric acid, thereby releasing larvae into the small intestine, where they penetrate the intestinal wall and enter the portal circulation. The larvae migrate to the pulmonary vasculature, where they penetrate the alveoli, ascend the bronchial tree, and are swallowed back into the intestinal tract, where they develop into adult worms 9 to 11 weeks after egg ingestion.[2] Each day, a female adult *Ascaris* worm releases over 200,000 eggs that are expelled in feces. Fertilized eggs (Fig. 327-2) become infectious after embryonating in warm, moist, shady soil. Eggs are resistant to extreme temperatures and to desiccation, and they can survive up to 15 years in the environment.

Clinical manifestations are associated with heavy worm burdens and result from larval migration through the lungs and from parasitism of the gastrointestinal tract by adult worms. During the pulmonary phase of the life cycle, *A. lumbricoides* larvae can induce an intense reaction that is due to both physical disruption and a hypersensitivity response to secreted antigens. This phenomenon is more common in areas in which transmission is seasonal, such as on the Arabian Peninsula, where outbreaks of pneumonitis typically follow the rainy season because of resumption of transmission.

CLINICAL MANIFESTATIONS

Low-intensity *A. lumbricoides* infections are usually asymptomatic, but heavy worm burdens cause symptoms including sudden onset of wheezing, dyspnea, paroxysmal nonproductive cough, and high fever. Symptoms may persist for 2 to 3 weeks before resolving spontaneously. Respiratory symptoms may coincide with or be preceded by urticarial rash, angioedema, abdominal pain, and vomiting.

With moderate or heavy infections, a mass of worms can cause obstruction in the small intestine or migration of worms to the biliary tree, pancreatic duct, or appendix. Intestinal obstruction, which is more common in young children because of their smaller lumen size, is characterized by colicky abdominal

ABSTRACT

Nematodes of medical importance can be categorized into those that primarily affect the gastrointestinal tract, where adult worms become established and cause disease, and those that affect other tissues and organ systems. The former group includes the roundworm *Ascaris lumbricoides*, the hookworms *Ancylostoma duodenale* and *Necator americanus*, the pinworm *Enterobius vermicularis*, the whipworm *Trichuris trichiura*, and the threadworm *Strongyloides stercoralis*. Nematodes that invade and cause disease primarily in tissues outside the gastrointestinal tract include those that cause lymphatic filariasis (*Wuchereria bancrofti, Brugia malayi*, and *Brugia timori*), *Onchocerca volvulus, Loa loa*, and the guinea worm *Dracunculus medinensis*, as well as *Trichinella* and *Angiostrongylus* species. Nematode infections are prevalent in the temperate and tropical regions of Africa, Asia, and Latin America. They are transmitted by the oral ingestion of embryonated eggs or by penetration of infective larvae through the skin, either by direct contact with contaminated soil or by the bite of an arthropod vector. Nematode infections are most common in areas with poor sanitation, where the environment is contaminated by human feces, and in climates that support survival of the insect vector if one is involved in the life cycle. Nematode infections are rarely fatal; they more commonly result in chronic morbidity such as iron deficiency anemia caused by hookworm or blindness due to onchocerciasis.

pain and vomiting that may progress to signs of intestinal perforation and be confused with acute appendicitis (Chapter 128). Hepatobiliary and pancreatic ascariasis are more common in adults. Chronic intestinal infection can manifest as abdominal pain and distention, diarrhea, and nausea. More insidious effects, especially in children, include decreased protein and fat absorption, development of vitamin A and C deficiencies, and lactose intolerance, which together lead to asthenia, stunted growth, and impaired cognitive development.

DIAGNOSIS

Diagnosis of ascariasis is usually made by microscopic examination of a sample of feces for characteristic thick-shelled eggs. Polymerase chain reaction (PCR) testing, although currently available only in specialized laboratories as a research tool, is also highly sensitive and specific.[3] However, during the pulmonary phase of infection, ova will not be detectable in feces because adult worms have not yet matured and begun producing eggs; instead, larvae, as well as eosinophils or Charcot-Leyden crystals (formed from the breakdown of eosinophils), may be visualized on microscopic examination of sputum. Pulmonary disease is also usually characterized by peripheral eosinophilia and transient infiltrates on chest radiographs. The diagnosis of intestinal or biliary obstruction caused by *A. lumbricoides* is usually made by ultrasound examination or endoscopic retrograde cholangiopancreatography (ERCP).

TREATMENT

Intestinal ascariasis is usually cured with a single oral dose of albendazole (Table 327-1).[A1] Alternatives include mebendazole, ivermectin,[A2] moxidectin, tribendimidine, or pyrantel pamoate. No specific treatment is recommended for symptoms of pulmonary ascariasis since the condition is self-limited. In severe cases of biliary obstruction, including cholangitis, ERCP with or without resection of the ampulla of Vater is highly successful and may preclude the need for surgery.

PREVENTION

The definitive means of preventing *Ascaris* infection is improvement of hygiene and proper disposal of human waste.[4] In endemic communities where this is not feasible, morbidity control consists of regular (usually annual) mass administration of an anthelminthic medication such as albendazole or mebendazole to preschool and school-aged children.

TABLE 327-1 ORAL TREATMENT OF INTESTINAL NEMATODES

NEMATODE	TREATMENT
Ascaris lumbricoides	Albendazole 400 mg once. Alternatives: mebendazole 500 mg once or 100 mg bid for 3 days, ivermectin 150-200 µg/kg once, moxidectin 8 mg once, or pyrantel pamoate 11 mg/kg once with the maximum dose not to exceed 1 g
Hookworm (*Necator americanus* and *Ancylostoma duodenale*)	Albendazole 400 mg daily for 3 days. Alternatives: tribendimidine 400 mg once; mebendazole 500 mg daily or 100 mg bid for 3 days; or pyrantel pamoate 11 mg/kg for 3 days with the maximum daily dose not to exceed 1 g
Cutaneous larva migrans (*Ancylostoma caninum* and *Ancylostoma braziliensis*)	Ivermectin 200 µg/kg daily for 1-2 days. Alternative: albendazole 400 mg daily for 3 days
Trichuris trichiura	Albendazole 400 mg daily for 3 days. Alternative: mebendazole 100 mg bid for 3 days. The addition of ivermectin 200 µg/kg or moxidectin 8 mg daily for 3 days improves efficacy
Enterobius vermicularis	Pyrantel pamoate 11 mg/kg once, with a second dose 2 wk later; maximum dose of 1 g. Alternatives: mebendazole 100 mg once or albendazole 400 mg once, repeated in 2 wk
Strongyloides stercoralis	Uncomplicated infection: ivermectin 200 µg/kg daily for 2 days.* Alternative: albendazole 400 mg bid for 7 days
Trichostrongylus spp	Pyrantel pamoate 11 mg/kg once; maximum dose of 1 g. Alternatives: albendazole 400 mg daily for 10 days or mebendazole 500 mg daily for 10 days
Capillaria philippinensis	Albendazole 400 mg bid for 10 days. Alternative: mebendazole 500 mg daily for 20 days

*Treatment may need to be extended in immunocompromised patients with disseminated disease.
bid = twice daily; spp = species.

PROGNOSIS

Untreated, ascariasis may lead to chronic infection that persists for years and can result in clinical complications ranging from rarely fatal intestinal or biliary obstruction to more insidious sequelae such as malnutrition. Although treatment with albendazole is highly effective, children living in endemic communities often become reinfected within months owing to continued exposure from the contaminated environment.

HOOKWORM

The Pathogen

Hookworm infection in humans is due almost exclusively to two species: *N. americanus* and *A. duodenale*. However, incidental infection with the zoonotic hookworms *Ancylostoma caninum*, *Ancylostoma braziliensis*, *Bunostomum phlebotomum*, and *Uncinaria stenocephala* can cause self-limited dermatologic lesions known as cutaneous larva migrans (Fig. 327-3). Additionally, *Ancylostoma ceylanicum*, normally a hookworm infecting cats, has been reported to cause intestinal disease in humans, especially in Asia, whereas *A. caninum* has been implicated as a cause of eosinophilic enteritis.

EPIDEMIOLOGY

Over 400 million people are infected with hookworms worldwide. *N. americanus* is widespread, whereas infection with *A. duodenale* is more geographically restricted. The highest prevalence of infection occurs in rural areas of tropical and less developed countries, where environmental and socioeconomic conditions favor transmission. Like *A. lumbricoides*, hookworm eggs require soil of adequate moisture and warm temperature to incubate and develop into larvae. Equally important determinants of infection are poverty and lack of access to adequate sanitation and clean water. The prevalence of infection increases with age in children living in endemic areas until it plateaus by about age 10 years. By comparison, the intensity of infection rises at a slower rate during childhood, reaching a plateau by about age 20 years and then increasing again in the elderly.

Although cutaneous larva migrans is found throughout the tropics, in the United States it is diagnosed primarily in travelers who have recently returned from a tropical beach vacation, especially in the Caribbean, South and Central America, and Southeast Asia. Occasionally, autochthonous cases (originating where found) have been reported in the United States, usually from southeastern coastal states such as Florida and Texas. Cutaneous larva migrans occurs when larvae of the dog or cat hookworms (*A. caninum* or *A. braziliense*, respectively) are expelled in their feces, contaminate moist soil or sand, and then come into contact with exposed skin. Other animal hookworms such as *U. stenocephala* and *B. phlebotomum* are less common causes.

FIGURE 327-3. Typical lesion of cutaneous larva migrans. An erythematous, serpiginous track caused by intradermal migration of a dog (*Ancylostoma caninum*) or cat (*Ancylostoma braziliense*) hookworm larva is apparent. (Reproduced with permission from Gregory L. Zalar.)

PATHOBIOLOGY

Infection occurs when exposed skin comes in contact with infective filariform larvae in fecally contaminated soil or grass. Larvae penetrate the skin and enter the venous circulation. After reaching the pulmonary vasculature, larvae penetrate into alveolae, ascend the bronchial tree to the larynx, and are swallowed into the gastrointestinal tract. Larvae develop into sexually mature adult worms 5 to 9 weeks after skin penetration. Adult hookworms reside in the lumen of the small intestine, where they attach to the mucosa by means of cutting teeth (*A. duodenale*) or a rounded cutting plate (*N. americanus*). After mating, female worms produce eggs that are expelled from the body in feces; *A. duodenale* female worms lay approximately 28,000 eggs daily, whereas the output from *N. americanus* worms averages around 10,000 a day. Hookworm eggs hatch in warm, moist, sandy soil and release larvae that can infect another host. Humans are the only natural definitive hosts for these two parasites, and there are no intermediate or reservoir hosts. *A. duodenale* worms survive on average for 1 year in the human intestine, whereas *N. americanus* lives for 3 to 5 years.

The major pathology of hookworm infection is the associated gastrointestinal blood loss and resulting iron deficiency anemia. Hookworms attach to the intestinal mucosa and secrete enzymes that enable them to invade submucosal tissues and ingest villous tissue and blood. Hemoglobinases within the hookworm's digestive canal degrade host hemoglobin for use as an essential nutrient source. The amount of blood loss is directly related to the total worm burden. *A. duodenale* causes more blood loss than *N. americanus*: each *N. americanus* worm results in a daily blood loss of 0.03 to 0.1 mL, whereas the corresponding figure for *A. duodenale* is between 0.15 and 0.26 mL.

CLINICAL MANIFESTATIONS

The clinical features of hookworm infection are related to the initial larval migration through the skin and other tissues and the acute and chronic manifestations resulting from parasitism of the gastrointestinal tract by adult worms. Repeated skin exposure to hookworm larvae can result in a hypersensitivity reaction known as "ground itch," a pruritic erythematous and papular rash that appears most commonly on the hands and feet. In contrast, when zoonotic hookworm larvae penetrate the skin to produce cutaneous larva migrans, most commonly on the feet, legs, and buttocks, they are unable to complete their life cycle in the human host and eventually die after causing a typical rash consisting of intensely pruritic, erythematous serpiginous tracks (see Fig. 327-3). Tracks appear after an incubation period of a few days, can be single or multiple, and advance by millimeters to a few centimeters each day. Vesiculobullous or papular lesions may develop along the tracks, as can secondary bacterial infection because of scratching. Untreated, lesions usually heal spontaneously within weeks to months following death of the larvae in the skin.

Migration of hookworm larvae through the lungs may induce mild and transient pulmonary symptoms consisting of dry cough, sore throat, wheezing, and low-grade fever. Uncommonly, acute symptomatic disease may follow the oral ingestion of *A. duodenale* larvae, known as Wakana syndrome, which is characterized by pharyngeal irritation, cough, dyspnea, hoarseness, nausea, and vomiting.

Gastrointestinal symptoms and signs caused by hookworm infection are uncommon. Instead, the manifestations of hookworm disease occur when intestinal blood loss exceeds the nutritional reserves of the host and results in iron deficiency anemia. Usually only moderate- and high-intensity (≥2000 eggs per gram of feces) hookworm infections produce clinical disease, which resembles that of iron deficiency anemia secondary to other causes (Chapter 145). In addition, the protein losses associated with heavy hookworm infection can result in hypoproteinemia and anasarca. Clinical manifestations of iron deficiency anemia include weakness, palpitations, fainting, dizziness, dyspnea, lassitude, and headache. Uncommonly, patients may have constipation or diarrhea with occult blood in the stool or even frank melena, especially in children; there may also be an urge to eat soil (pica). Overwhelming hookworm infection may cause listlessness, coma, and even death, especially in infants. Because children and women of reproductive age have lower iron reserves, they are at increased risk of symptomatic disease.

DIAGNOSIS

The diagnosis of hookworm infection is made by microscopic identification of characteristic eggs in the stool. The eggs of *N. americanus* and *A. duodenale* cannot be distinguished because both are colorless and have a single thin hyaline shell with blunted ends; they range in size from 55 to 75 μm by 36 to 40 μm. Egg concentration techniques, such as the formalin–ethyl acetate sedimentation method, can be used to detect even light infections, although a direct wet mount examination is adequate for detecting moderate to heavy infections. As with *A. lumbricoides*, PCR testing that has been reported to be highly sensitive and specific is performed by a few specialized laboratories but is not commercially available or approved as a diagnostic test. In addition, eosinophilia is a common finding in chronic infection and during larval migration through the lungs.

TREATMENT

For intestinal hookworm infection, three daily oral doses of albendazole 400 mg is the recommended treatment (see Table 327-1). Tribendimidine, which is not FDA approved and is not available or approved in most countries, has a similar efficacy profile as albendazole as a single oral dose of 400 mg, alone or in combination with other anthelminthics, such as single-dose ivermectin or oxantel pamoate.[A3] Less effective alternatives include mebendazole, pyrantel pamoate, and single-dose albendazole. Iron supplementation is recommended in patients with significant or symptomatic anemia.

For cutaneous larva migrans, although the disease is self-limited and will resolve spontaneously within weeks to a few months, treatment with one to two daily doses of ivermectin (200 μg/kg) leads to faster resolution of symptoms and skin manifestations. Albendazole is an alternative treatment of cutaneous larva migrans.

PREVENTION

The ideal method for preventing hookworm infection is improvement in hygiene and proper disposal of human waste. In endemic communities where these public health measures have not been accomplished, control of disease consists of regular (at least annual) mass administration of single doses of an anthelminthic medication such as albendazole or mebendazole. For cutaneous larva migrans, tourists should be advised to wear shoes or sandals when walking on beaches and to avoid areas frequented by stray cats and dogs.

PROGNOSIS

Severe iron deficiency anemia caused by hookworm during pregnancy can result in adverse consequences for the mother, the fetus (spontaneous abortion, intrauterine growth restriction), and the neonate (anemia, failure to thrive). In children, the anemia and protein malnutrition (Chapter 197) associated with chronic infection cause long-term deficits in physical and cognitive development.

TRICHURIASIS

The Pathogen

T. trichiura nematodes, or whipworms, which grow to as long as 50 mm, spend their entire life cycle in the host's gastrointestinal tract.

EPIDEMIOLOGY

The estimated worldwide prevalence of trichuriasis is 465 million, most commonly in poor, rural areas of the tropics and subtropics where disposal and treatment of human waste are inadequate. Children are more frequently infected than adults and more likely to have higher worm burdens. Humans are the only host.

PATHOBIOLOGY

T. trichiura does not have a tissue migratory phase like *A. lumbricoides* and hookworm. After embryonated eggs are ingested orally, they hatch and release larvae into the proximal large intestine, where they undergo a series of molts before being carried passively to the transverse and descending colon. The adult worm's narrow anterior end embeds in the columnar epithelium, while the posterior portion protrudes into the lumen. After mating, female worms expel unembryonated eggs into the feces, which are then passed into the environment, where they must embryonate in warm, moist soil to complete the life cycle. Adult worms can survive in the host for approximately 1.5 to 2 years. The period between ingestion of eggs and detection of eggs in feces is about 90 days.

CLINICAL MANIFESTATIONS

Most *T. trichiura* infections are asymptomatic. Symptomatic disease occurs primarily in children because most heavy infections (>10,000 eggs per gram of feces) occur in this age group. Heavy infections can manifest as an acute dysentery or as a chronic colitis resembling inflammatory bowel disease with recurrent abdominal pain and diarrhea.

DIAGNOSIS

Infection is diagnosed by microscopic identification of the typical barrel-shaped eggs with bipolar plugs in direct or concentrated smears of fecal specimens. PCR testing has been reported to be highly sensitive and specific by a few specialized laboratories but is not commercially available or approved as a diagnostic test.

TREATMENT

T. trichiura responds less effectively than *A. lumbricoides* or hookworm to treatment with single-dose albendazole or mebendazole, so a 3-day course of either benzimidazole drug is recommended (see Table 327-1). The addition of ivermectin (200 µg/kg) to either drug can increase the response rate significantly.[A4] Some data also indicate that the combination of moxidectin (8 mg) plus albendazole may be more effective than albendazole alone.[A5]

PREVENTION

As for *A. lumbricoides* and hookworm, control of trichuriasis in endemic areas consists of regular mass anthelminthic drug administration, primarily to preschool and school-aged children. Although the single doses of albendazole or mebendazole that are used in most mass drug administration programs worldwide are poorly effective for this intestinal nematode, their use is still recommended by the World Health Organization.

PROGNOSIS

Chronic mucosal inflammation and edema of the colon and rectum can lead to protracted tenesmus that can result in rectal prolapse. Chronic *Trichuris* colitis can also lead to malnutrition, impaired growth, and anemia.

ENTEROBIASIS

The Pathogen

E. vermicularis, or pinworm, is transmitted by the fecal-oral route. Adult worms measure from 2 to 5 mm.

EPIDEMIOLOGY

E. vermicularis is found worldwide and is the most prevalent nematode infection in temperate climes. Transmission is frequent in primary schools and daycare centers.

PATHOBIOLOGY

After ingestion, embryonated eggs hatch in the small intestine, where larvae develop into adult worms that migrate to the large intestine, where they mate. Gravid female worms emerge nightly from the anus to deposit large numbers of eggs (11,000 per worm) on the perianal and perineal skin, where they embryonate within 6 hours. If they are still on the skin, infective larvae are released and can migrate back through the anus into the rectum (retroinfection). Alternatively, autoinfection occurs when eggs are transferred to the mouth via scratching skin on which eggs have been deposited. Larvae may also migrate into the female genital tract and establish ectopic infection.

CLINICAL MANIFESTATIONS

Although pinworm infections may be asymptomatic, perianal pruritus is the most common symptom and is due to an allergic response to worm proteins. The pruritus can be intense and result in chronic sleep deprivation in children. Rarely, adult *E. vermicularis* may precipitate appendicitis. When hatched larvae migrate into the female genital tract, vulvovaginitis, salpingitis, or peritonitis may develop.

DIAGNOSIS

Pinworm infection is diagnosed by identifying the characteristic eggs through microscopic examination of a piece of cellophane tape applied to the perianal region immediately after waking in the morning. *E. vermicularis* eggs are oval and slightly flattened on one side. Eggs are not usually found in fecal samples. Repeated examination may be necessary.

TREATMENT

Pinworm infection is treated with a single dose of pyrantel pamoate, mebendazole, or albendazole, which must be repeated 2 weeks later because the drugs do not kill eggs or developing larvae (see Table 327-1). Given the high rate of transmission, all household members and individuals in close contact with the patient (e.g., other children attending the same daycare center) should also be treated. Bedding and underclothes should be thoroughly laundered in hot water followed by a hot dryer to kill remaining eggs.

PROGNOSIS

Enterobiasis usually does not result in severe manifestations, particularly in children, and it responds rapidly to appropriate treatment.

STRONGYLOIDIASIS

The Pathogen

S. stercoralis, commonly known as threadworm, is endemic in warm climates worldwide, including parts of the United States. Adult males are about 0.75 mm long, and adult females are about 1.0 mm long.

EPIDEMIOLOGY

S. stercoralis infection is endemic in the tropical and subtropical regions of sub-Saharan Africa, Asia, Latin America, and areas of Eastern and Southern Europe, with a worldwide prevalence of up to 100 million. In the United States, *Strongyloides*-related hospitalizations are rare,[5] and infection is diagnosed most frequently in immigrants; however, strongyloidiasis is still endemic in parts of rural Appalachia. *S. stercoralis* can also be transmitted sexually through oral-anal contact, most often among men who have sex with men, or via transplantation of solid organs.

PATHOBIOLOGY

Infection occurs when exposed skin comes in contact with free-living filariform larvae in soil contaminated with human feces. Like hookworm, larvae penetrate the skin, enter the vasculature, and migrate to the pulmonary capillaries, where they penetrate into the alveoli, ascend the bronchial tree to the pharynx, and are swallowed into the gastrointestinal tract. Further development into adult worms occurs in the upper small intestine, where parasites live embedded in the mucosa. Unlike most nematodes, *S. stercoralis* reproduces by parthenogenesis, with no apparent parasitic male worm present in the human host. Within 25 to 30 days after infection, female worms begin laying eggs, which rapidly hatch in the intestinal lumen and release noninfectious rhabditiform larvae that migrate to the colon and are excreted in feces. Alternatively, larvae may penetrate the colonic mucosa or perianal skin after migrating out of the anus and enter the circulation directly, a mechanism known as autoinfection that can lead to maintenance of parasitism in the host for decades.

In the soil, infectious filariform larvae can be produced either directly via transformation from rhabditiform larvae or indirectly from eggs released by free-living adult worms that have developed from rhabditiform larvae in warm, moist, sandy soil.

In immunologically competent individuals, infection does not usually result in symptomatic disease. However, serious complications may occur in individuals with cell-mediated immunodeficiency such as patients chronically taking corticosteroids, solid organ transplant recipients, patients with hematologic malignancies, or patients infected with human T-cell lymphotropic virus type 1. In these patients, the *S. stercoralis* autoinfection cycle can become amplified and lead to a hyperinfection syndrome with a large increase in the total worm burden in the infected person. Hyperinfection can lead to life-threatening dissemination of larvae and adult worms to aberrant sites such as the brain, pancreas, and kidneys. For unknown reasons, acquired immunodeficiency syndrome (AIDS) has not been associated with hyperinfection syndrome or with disseminated strongyloidiasis.

CLINICAL MANIFESTATIONS

Most *S. stercoralis* infections, especially in immunocompetent hosts, are asymptomatic or are associated with only mild gastrointestinal symptoms such as abdominal pain, bloating, and watery diarrhea. Gastrointestinal bleeding, manifested by hematochezia or melena, occurs in less than 20% of those infected. Rare causes of morbidity include small bowel obstruction, paralytic ileus, and a malabsorption syndrome (especially in children).

During the migratory phase of larvae through the lungs, symptoms are rare in immunocompetent patients, although there may be peripheral eosinophilia. In immunocompromised persons with hyperinfection syndrome, however, pulmonary signs and symptoms can be severe and resemble those of adult respiratory distress syndrome (Chapter 90) with acute onset of dyspnea, productive cough, and hemoptysis accompanied by fever, tachypnea, and hypoxemia. Disseminated strongyloidiasis is frequently accompanied by bacterial sepsis due to translocation of enteric organisms carried by migrating larvae.

Migration of filariform larvae from the anus can lead to a dermatologic manifestation known as larva currens, which is characterized by migratory serpiginous erythematous maculopapular tracks, primarily on the skin of the buttocks, groin, and lower abdomen.

Autoinfection leading to exceptionally high worm loads (i.e., hyperinfection) and disseminated strongyloidiasis can occur in persons with deficient cell-mediated immunity. Because asymptomatic infection with *S. stercoralis* can persist for decades after initial infection, a change in immune status associated with conditions such as the administration of immunosuppressive drugs following solid organ transplantation may result in hyperinfection syndrome even though the infection was previously asymptomatic. Massive increases in the number of *Strongyloides* larvae because of hyperinfection can present as acute enteritis with severe diarrhea and ulcerative disease of the small and large intestine. During disseminated infection, larvae and sometimes adult worms penetrate the intestinal mucosa, migrate to aberrant sites, including the central nervous system, and result in metastatic abscesses and gram-negative meningitis due to enteric bacteria being carried by the migrating parasites. Less common complications of disseminated disease include glomerulonephritis and minimal-change nephrotic syndrome, acute respiratory distress syndrome, and alveolar hemorrhage.[6] Swollen belly syndrome, a less common type of strongyloidiasis seen in infants living in Central Africa and Papua New Guinea, has been attributed to infection with *Strongyloides fuelleborni*, which is normally a zoonosis of nonhuman primates.

DIAGNOSIS

Definitive diagnosis of *S. stercoralis* infection relies on microscopic identification of larvae in feces or other fluids (such as sputum) or tissues.[7] Intestinal strongyloidiasis can be diagnosed by observation of larvae in direct smears of freshly passed stool. The sensitivity of microscopy on a single fecal sample examination is as low as 30% but can be increased by examining multiple fecal specimens, by using concentration techniques, and by plating feces on an agar plate and inspecting for tracks of colonies created by bacteria being dragged by migrating larvae. Several molecular amplification techniques have been developed by various research laboratories, but none has been approved for clinical use.

Hyperinfection syndrome and disseminated strongyloidiasis can be diagnosed by detection of filariform larvae in duodenal fluid obtained by endoscopy, in sputum, or in bronchoalveolar lavage specimens. Larvae have also been recovered from cerebrospinal fluid, urine, peritoneal washings, skin, and the brains of immunocompromised persons.

Fluctuating eosinophilia is common with uncomplicated intestinal strongyloidiasis, especially during the pulmonary migration phase of initial infection. However, eosinophilia may be absent in patients with hyperinfection and dissemination. In fact, patients with hyperinfection and eosinophilia have a better prognosis than do those without eosinophilia.

Serologic diagnosis using an enzyme-linked immunosorbent assay (ELISA) that detects antibodies to filariform larvae is very sensitive, even in immunocompromised hosts with disseminated strongyloidiasis, although some false positives may occur in cases of co-infection with other nematodes, particularly filaria. Specificity is improved by using the newer luciferase immunoprecipitation system (LIPS) assays that incorporate *Strongyloides*-specific recombinant antigens. LIPS assays have the additional advantage of rapidly reverting to being seronegative following successful treatment.

TREATMENT

Uncomplicated intestinal strongyloidiasis can be treated effectively with ivermectin (200 µg/kg body weight daily for 2 days), with cure rates exceeding 90%.[A6] Albendazole is an alternative treatment (see Table 327-1),[A7] and moxidectin (8 mg) also has shown promising results.[8] Decreases in antibody titer and eosinophil count indicate a response to treatment in the absence of re-exposure. After 6 months, ELISA titers should decrease significantly, whereas LIPS assays should revert to negative.

In immunocompromised patients with hyperinfection or disseminated disease, ivermectin should be administered daily. Some experts recommend continuing treatment until 2 weeks after fecal examinations have become negative (i.e., for one autoinfection cycle). For severely ill patients who are unable to tolerate oral therapy, ivermectin enemas have been used. Combination therapy with ivermectin and albendazole may also be used to treat disseminated strongyloidiasis, but whether this combination improves prognosis over monotherapy is unknown.

PREVENTION

In endemic areas, the risk for infection can be reduced by minimizing skin contact with contaminated soil, although elimination of this infection will occur only with improvements in sanitation and treatment of human waste. To prevent hyperinfection in individuals who have unrecognized chronic infection, diagnosis should be attempted before the onset of immunosuppression if possible, such as before organ transplantation or cancer chemotherapy. Anyone who has resided in or traveled to an endemic area should undergo screening for asymptomatic infection, preferably by serology or, if not possible, by microscopic examination of at least three fecal samples for the presence of larvae. Patients with positive screening test results should be treated empirically with ivermectin. Individuals with negative screening test results but unexplained eosinophilia and a history of exposure should also be considered for empirical treatment. In patients undergoing hematopoietic stem cell transplantation, documentation of cure with at least three consecutive negative fecal examinations or a negative LIPS assay is recommended before proceeding with transplantation.

PROGNOSIS

Uncomplicated strongyloidiasis is rarely fatal and responds rapidly to effective treatment without permanent sequelae. Although hyperinfection and disseminated disease occur in only a minority of cases, mortality rates can exceed 85%, mostly due to the accompanying bacterial sepsis. However, early diagnosis and prompt initiation of treatment for this severe form of the infection are associated with improved outcomes.

UNCOMMON INTESTINAL NEMATODIASES

Humans may serve as incidental hosts for some nematodes that ordinarily parasitize the intestines of other mammals.

TRICHOSTRONGYLUS

Human infections with various species of the genus *Trichostrongylus* have been reported in Iran, the Far East, and Australia. Humans become infected when larvae are ingested with leafy vegetables that have been contaminated with soil containing the feces of herbivorous animals. *Trichostrongylus* worms are similar to hookworms in their morphology, appearance of their eggs on fecal examination, and the pathology that they induce. Heavy infections may be accompanied by diarrhea and anemia. Drugs recommended for treatment are pyrantel pamoate, albendazole, and mebendazole (see Table 327-1).

ANISAKIASIS

Anisakiasis results from ingestion of the larvae of nematodes that normally infect sea mammals such as dolphins, whales, and seals. Larvae of the genera *Anisakis*, *Phocanema*, and *Pseudoterranova* infect the flesh of several saltwater fish species as intermediate hosts. Consumption of raw or undercooked fish, often in the form of sushi or sashimi, results in release of the infective larvae into the stomach, followed by invasion of the stomach or duodenal wall, which causes upper abdominal pain that can be intense. Anisakid worms cannot further develop in humans and die within a few days; an eosinophilic granulomatous reaction that mimics a gastric tumor may result. Diagnosis and treatment are accomplished by endoscopic removal of the parasite. Infection is prevented by cooking or freezing seafood before consumption. Of note, salting, smoking, and marinating fish do not kill anisakid larvae.

CAPILLARIA PHILIPPINENSIS

C. philippinensis can cause a serious intestinal infection that has been reported primarily in the Philippines and Thailand, although cases have also been observed in Japan, Taiwan, Korea, and Egypt. Adult worms resemble those of *Trichinella spiralis*, although biologically they mimic *S. stercoralis* in that they have an autoinfection cycle of reproduction in which larvae can develop into adult worms without leaving the host. Even though the life cycle has not been completely elucidated, this nematode probably parasitizes waterfowl that feed on fish and crustaceans, which serve as intermediate hosts. Humans become infected by eating raw or undercooked infected shrimp or fish. Adult worms migrate to the mucosal crypts of the small intestine, where they deposit larvae, sometimes resulting in overwhelming infection. Clinical disease consists of severe diarrhea associated with anorexia, vomiting, and weight loss. Diagnosis depends on visualizing eggs or larvae in feces. The treatment of choice is albendazole or mebendazole (see Table 327-1). Mortality rates as high as 10% have been reported, with death resulting from severe malabsorption and protein-losing enteropathy.

TISSUE NEMATODE INFECTIONS

The tissue nematodes can be divided into organisms for which humans are the principal host (the filariases) and zoonotic organisms that usually infect

animals but can incidentally infect humans. Zoonotic nematodes such as *Toxocara*, *Trichinella*, and *Angiostrongylus* infect humans following accidental oral ingestion of eggs or larvae but are unable to complete their life cycle in the host. Clinical manifestations are primarily due to the aberrant migration of larvae through various tissues.

TOXOCARIASIS

DEFINITION

Accidental ingestion of embryonated eggs of the dog roundworm *Toxocara canis* or, less frequently, the cat ascarid *Toxocara cati* can cause the clinical syndromes of visceral larva migrans and ocular larva migrans. Symptoms, which are caused by the migration of larvae through the organs of the body, can result in serious disease and even death.

EPIDEMIOLOGY

Toxocara infections in animals are ubiquitous throughout the world. In humans, children are most frequently infected, probably due to ingestion of soil contaminated with dog or cat feces when playing outside. Visceral larva migrans occurs most commonly in children younger than 5 years, whereas ocular larva migrans typically manifests in older children between the ages of 5 and 10 years.

PATHOBIOLOGY

The life cycle of *Toxocara* in the animal host resembles that of *A. lumbricoides* in humans; larvae penetrate the intestinal wall after being released from ingested eggs, migrate through the vasculature to the lungs, enter the alveolae, and ascend the bronchial tree until they are swallowed back into the gastrointestinal tract, where they develop into adult worms that can produce eggs. However, when embryonated *Toxocara* eggs are ingested by humans, the released larvae migrate throughout the body (most commonly to the lungs, the liver, the central nervous system [CNS], and occasionally the eyes) but cannot develop into adult worms. When the larvae eventually die, they induce significant immediate-type and delayed-type hypersensitivity reactions that result in the formation of eosinophilic granulomas. Visceral larva migrans and ocular larva migrans seem to be mutually exclusive.

CLINICAL MANIFESTATIONS

Most *Toxocara* infections in humans are asymptomatic. Visceral larva migrans is characterized by low-grade fever, pulmonary symptoms (including cough and wheeze), and, less frequently, hepatosplenomegaly that sometimes causes right upper quadrant pain. Symptoms appear gradually and resolve slowly over 4 to 8 weeks. Myocarditis, nephritis, and CNS disease are less common. CNS involvement can result in seizures, encephalopathy, neuropsychiatric symptoms, or an eosinophilic meningoencephalitis.[9]

Ocular larva migrans typically presents as unilateral visual impairment that is sometimes accompanied by strabismus. Ocular larva migrans involving the retina can be difficult to distinguish from other causes of focal intraretinal lesions, such as retinoblastoma or tuberculosis.

DIAGNOSIS

Toxocariasis can be presumed based on a compatible clinical presentation and history of exposure to dogs or cats. Eosinophilia and hypergammaglobulinemia are often present. Serologic testing using an ELISA in combination with immunoblot to detect antibodies to *Toxocara* larval-stage antigens may be informative, but does not distinguish between active infection and past exposure. ELISAs incorporating recombinant larval antigens have improved sensitivity and specificity but are not yet widely available.[10] PCR testing is not currently available, and tissue biopsy to document the presence of larvae also is not recommended because of low sensitivity.

Computed tomography and fluorescein angiography may be helpful in the diagnosis of ocular larva migrans, especially to differentiate it from retinoblastoma and other causes of intraocular space-occupying lesions. Elevated levels of anti-*Toxocara* antibodies in aqueous and vitreous humor fluid relative to serum are also suggestive of this diagnosis.

TREATMENT

Albendazole (400 mg given twice daily for 5 days) is recommended for acute toxocariasis (Table 327-2). In patients who have severe pulmonary, cardiac, or neurologic involvement, corticosteroids (e.g., prednisone 60 mg daily for 5 days) may reduce the severity and duration of symptoms. Ocular larva migrans is treated by vitrectomy, corticosteroids (e.g., prednisone 30 to 60 mg daily for 2 weeks), albendazole, or a combination of these with expert supervision.

TABLE 327-2 TREATMENT OF TISSUE NEMATODE INFECTIONS

NEMATODE INFECTION	TREATMENT
Toxocariasis	Albendazole 400 mg bid for 5 days
Trichinellosis	Albendazole 400 mg bid for 8-14 days*
Angiostrongyliasis	Treatment with albendazole 15 mg/kg/day or mebendazole 10 mg/kg/day for 14 days is controversial but may relieve symptoms.
Gnathostomiasis	Albendazole 400 mg bid for 3 weeks Alternative: ivermectin 200 µg/kg/day for 2 days +/- surgical removal
Lymphatic filariasis	Diethylcarbamazine 6 mg/kg/day divided in three doses for 1 or 12† days plus doxycycline 200 mg/day for 6 weeks
Onchocerciasis	Doxycycline 200 mg/day for 6 weeks, preceded and followed by a single dose of ivermectin 150 µg/kg or moxidectin 8 mg (age >12 years) that is repeated every 3-6 months until resolution of symptoms and then annually for at least 3 years
Loiasis	Diethylcarbamazine 8-10 mg/kg/day divided in three doses for 21 days†,‡
Mansonella perstans	Doxycycline 200 mg/day for 6 weeks
Mansonella ozzardi	Ivermectin 200 µg/kg once
Mansonella streptocerca	Diethylcarbamazine 6 mg/kg/day divided into three doses for 12 days Alternative: ivermectin 150 µg/kg once
Dracunculiasis	Extraction of the adult worm

*Treatment is effective only if it is initiated during the intestinal phase of infection.
†Start at a dose of 50 mg on the first day, 50 mg three times/day on the second, 100 mg three times/day on the third, and then 8-10 mg/kg/day on day 4 onward.
‡Repeated treatment after 6 months is often necessary if symptoms and eosinophilia persist.
bid = twice daily.

PREVENTION

Visceral and ocular larva migrans may be prevented by periodic anthelminthic treatment of dogs and cats, proper disposal of pet feces, covering sandboxes, washing hands after playing with dogs or cats, and keeping children from playing in areas where animals have defecated.

PROGNOSIS

Symptoms of visceral larva migrans gradually resolve over 4 to 8 weeks, even in the absence of treatment. In ocular larva migrans, the degree of vision loss is dependent on the ocular structure involved, and permanent blindness may occur.

BAYLISASCARIASIS

Baylisascariasis is a rare zoonosis caused by infection with *Baylisascaris procyonis*, which is an ascarid parasite of raccoons and other small carnivores. In North America, infection is most associated with contact with raccoons or environments contaminated with their feces and occurs predominantly in infants and young children who ingest the embryonated eggs while playing with soil. Clinically, disease is manifested as neural larva migrans due to larval invasion of the CNS after release from ingested eggs in the gastrointestinal tract. Characteristic findings include fever, altered mental status, focal neurologic deficits, and seizures. Analysis of the cerebrospinal fluid (CSF) reveals eosinophilic meningitis. Once neural larva migrans is present, response to treatment with anthelminthics is poor, although corticosteroids may be helpful under expert supervision. *B. procyonis* has also been associated with ocular larva migrans, for which successful use of laser photocoagulation has been reported. Prophylactic albendazole (25 mg/kg/day for 20 days) started within days of an exposure may prevent clinical disease. Infection can be fatal or result in permanent neurologic or visual impairment.

TRICHINELLOSIS

DEFINITION

Trichinella infects a range of mammalian hosts, with the domestic pig serving as the most important reservoir worldwide. Humans are infected through eating raw or undercooked pork or other meats of domestic or wild animals that are contaminated with larvae that are encysted in muscle tissue. Although larvae develop into adults in the human intestinal tract, mate, and produce offspring larvae, clinical disease is characterized not so much by the intestinal infection

as by the newborn larvae that penetrate the intestinal wall and disseminate throughout the body.

EPIDEMIOLOGY

Several different species of *Trichinella* cause disease in humans, although *Trichinella spiralis* is the most common. *T. spiralis* is enzootic throughout the world in omnivorous and carnivorous wild animals, including bears, boars, and rats. *Trichinella nativa* affects predominantly carnivores (e.g., walruses, polar bears, and seals) living in the Arctic and subarctic regions of North America, Europe, and Asia. *Trichinella* is introduced into domestic animal populations, usually pigs or horses, by feeding them unprocessed meat scraps derived from infected animals, most commonly rats. Because of regulations banning this practice in the United States, Canada, and the European Union, human infection by consumption of undercooked or smoked pork products or beef contaminated with encysted larvae has been virtually eliminated, although it still occurs throughout the rest of the world. Instead, ingestion of poorly cooked wild game, especially bear or boar meat, is now the most common source of infection in these locations. In addition, an important source of infection with *T. nativa* in Alaskan and Canadian Arctic native populations is by eating uncooked walrus meat.

PATHOBIOLOGY

Trichinellosis results from ingestion of striated muscle containing encysted infective larvae. Larvae are released from muscle tissue by gastric enzymes and then migrate to the upper small intestine, where they rapidly develop into sexually mature adult worms after only 2 days. Adults live embedded in the columnar epithelium, where they grow to a length of 3 mm (females) or 1.5 mm (males). Females begin producing newborn larvae within 5 days of mating. Adult worms remain viable for an additional 3 to 5 weeks, after which acquired immunity leads to their expulsion from the host.

The oral cavity of newborn larvae possesses a swordlike stylet that permits them to penetrate the lamina propria, enter the lymphatic and blood vessels of the host, and migrate throughout the body. Larvae, which can enter all types of cells, usually die except in striated skeletal and cardiac muscle cells. Unique among nematodes, mature *Trichinella* larvae have an intracellular phase, during which they transform muscle cells into "nurse cells" that support larval growth and survival for decades (Fig. 327-4). Although nurse cells do not result in any disease in most mammals, in humans they can induce an eosinophilic granulomatous reaction that may result in significant tissue damage and symptoms.

As with most nematode infections, the severity of symptoms is related to the worm burden. Because newborn larvae are incapable of developing into adult worms within the human host, the number of encysted larvae ingested is the most important determinant of the number of larvae that invade muscle and other tissues.

CLINICAL MANIFESTATIONS

Clinical disease in humans progresses from an initial intestinal phase to a systemic or muscle phase. The initial phase of infection occurs within days after ingestion of larvae and may be associated with mild diarrhea, abdominal pain, and vomiting. This phase is self-limited and usually resolves spontaneously within 10 days.

The systemic dissemination of *Trichinella* larvae can result in myocardial, pulmonary, and focal neurologic manifestations, although usually only in heavily infected persons. This systemic phase of infection usually begins 2 to 3 weeks after ingestion of infective larvae and may persist for several weeks.

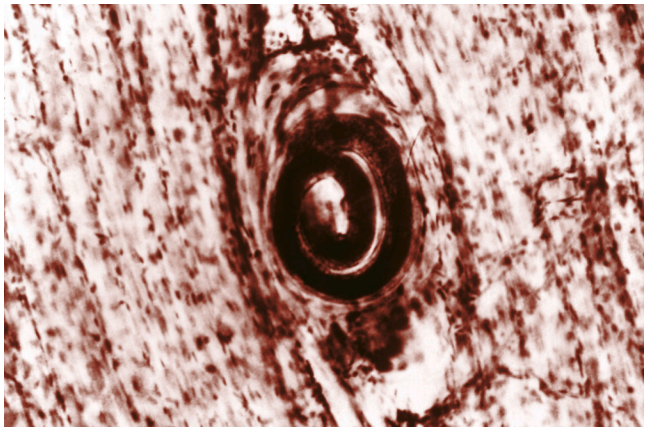

FIGURE 327-4. **Nurse cell in muscle tissue containing a larva of *Trichinella spiralis*.** (Courtesy of Dr. I. Kagan, Centers for Disease Control and Prevention.)

Clinical manifestations typically include fever, periorbital or facial edema, a diffuse inflammatory myositis (Chapter 248) that is characterized by myalgias and muscle tenderness, and petechial hemorrhages most easily observed in the subungual skin and conjunctivae. Larval invasion of the myocardium can lead to myocarditis (Chapter 47) that may result in heart failure or arrhythmias.

DIAGNOSIS

A diagnosis of trichinellosis should be suspected in individuals with a compatible clinical presentation, a history of eating raw or undercooked meat, eosinophilia, and increased muscle enzymes such as creatine kinase and lactate dehydrogenase. Definitive diagnosis depends on visualization of nurse cells in a muscle biopsy specimen or detection of *Trichinella*-specific DNA by PCR testing. Findings on muscle biopsy may be normal even in heavily infected patients because of sampling error. Detection of anti-*Trichinella* antibodies can be very useful in making a diagnosis, and antibodies can be detected as early as 12 days after initial infection.

TREATMENT

During the intestinal phase of infection, albendazole is recommended at a dosage of 400 mg given twice daily for 8 to 14 days to kill the adult worms and prevent release of newborn larvae (see Table 327-2). Administration of albendazole during the systemic phase of infection could potentially worsen symptoms by exacerbating the host inflammatory response to dying larvae, so treatment of severe systemic disease, including myocarditis and neurologic disease, should combine corticosteroids (e.g., prednisone 40 to 60 mg daily for 8 to 14 days), with albendazole. Symptomatic treatment with antipyretics and analgesics should also be considered.

PREVENTION

Trichinella infection is prevented by thoroughly cooking meat to kill encysted larvae. Freezing meat solid at –20° C for at least 3 days will kill *T. spiralis* but not all other species of *Trichinella*. Of note, curing and smoking techniques do not reliably kill this nematode.

PROGNOSIS

Although mortality due to trichinellosis is rare, larvae encysting in viscera may result in death due to cardiac, renal, hepatic, or cerebral complications. In most cases, however, fever and muscle pain usually resolve between 1 and 6 weeks after all migrating larvae have encysted in tissue.

ANGIOSTRONGYLIASIS

DEFINITION

Angiostrongylus cantonensis and *Angiostrongylus costaricensis* are nematodes that normally infect rodents, primarily rats.

EPIDEMIOLOGY

Human infections with *A. cantonensis* occur mainly in Southeast Asia and the South Pacific and less frequently in South America, the Caribbean, and in Louisiana. Abdominal angiostrongyliasis due to *A. costaricensis* has been reported mainly in Latin America, mostly in young children.

PATHOBIOLOGY

The adult worms of *A. cantonensis*, or rat lungworm, inhabit the pulmonary arteries of rodents. Larvae are produced and migrate to the pharynx, where they are swallowed, and then are passed in the feces. Mollusks such as snails, slugs, and prawns serve as intermediate hosts until they are ingested by definitive hosts. Released larvae migrate to the brain, where they develop into immature adult worms before traveling to the pulmonary vasculature to become sexually mature adults. Humans are incidentally infected after eating raw or poorly cooked mollusks or fresh vegetables contaminated with parts of infected mollusks; larvae can migrate to the CNS but cannot develop further. As opposed to *A. cantonensis*, the larvae of *A. costaricensis* can develop into sexually mature adult worms in the local lymphatics and mesenteric arterioles of humans and release eggs and larvae into the intestinal tissue, thereby causing an intense eosinophilic granulomatous reaction.

CLINICAL MANIFESTATIONS

After ingestion, *A. cantonensis* larvae penetrate the intestinal wall and migrate to the brain, the meninges, and, less commonly, the spinal cord and eye. Fever, severe headache, meningismus, nausea, vomiting, seizures, and focal neurologic deficits may develop. *A. costaricensis* infection can mimic appendicitis with right-sided abdominal pain, vomiting, and fever. Less frequently, gastrointestinal bleeding may occur.

DIAGNOSIS

Diagnosis of *A. cantonensis* infection is based on a history of ingestion of potentially contaminated food, the presence of eosinophilia, microscopic observation of eosinophils and, rarely, larvae in the CSF, and detection of the parasite by PCR in CSF.[11] In patients who have CNS and/or intestinal angiostrongyliasis, neither larvae nor eggs are found in the feces, although both may be seen in tissue specimens. Serology is not commercially available.

TREATMENT AND PREVENTION

The benefit of anthelminthics (Chapter 315) is unclear, although albendazole or mebendazole (Table 327-2), usually administered in combination with analgesics and corticosteroids (e.g., prednisone 60 mg daily for 14 days), appear to relieve symptoms. Serial lumbar punctures to remove CSF can relieve symptoms of raised intracranial pressure caused by infection with *A. cantonensis*. Proper cooking of food and washing of vegetables can prevent this infection.

PROGNOSIS

Most patients infected with either species of *Angiostrongylus* recover completely after approximately 2 weeks.

GNATHOSTOMIASIS

Gnathostoma spinigerum is an intestinal nematode of dogs and cats. Intermediate hosts include tiny crustaceans (copepods), amphibians, freshwater fish, and birds. Human infection occurs throughout the Far East, Thailand, and Latin America after eating raw or undercooked invertebrate hosts that contain infective larvae. The larvae are subsequently released into the intestine and migrate through the body without reaching sexual maturity. The most common clinical presentation is migrating painful and pruritic subcutaneous swellings. Eosinophilic meningitis and ocular larva migrans may also occur. Peripheral eosinophilia is usually present; with meningitis, eosinophils are also present in the CSF. Although serologic testing is not available in the United States, laboratories in Thailand and Japan can perform it. Treatment of cutaneous disease with either a 3-week course of albendazole or a 2-day course of ivermectin is recommended (see Table 327-2); for neurologic or ocular involvement, management is supportive, and anthelminthics are not advised because they may worsen manifestations. Gnathostomiasis may be prevented by thoroughly cooking fish. This infection may progress to potentially devastating results, including paralysis, subarachnoid hemorrhage, and permanent visual loss.

FILARIASES

DEFINITION

The filariases are arthropod-borne nematode infections in which mature adult worms live in the lymphatics or in connective tissue.

EPIDEMIOLOGY AND PATHOBIOLOGY

Eight filarial species infect humans, mostly in tropical areas of the world (Table 327-3): *Wuchereria bancrofti, Brugia malayi, Onchocerca volvulus, Brugia timori, Loa loa, Mansonella streptocerca, Mansonella perstans*, and *Mansonella ozzardi*. The first three are the most common filariases worldwide.

For all filarial nematodes, transmission to humans is via the bite of an infected arthropod vector that deposits infective larvae called microfilariae into the skin or blood. After several months, microfilariae mature into adult worms that are capable of mating to produce new microfilariae that can be ingested by another arthropod vector to complete the life cycle. Untreated, adult worms survive for 5 to 17 years in the human host; microfilariae live for between 5 months and 5 years. For most filarial nematodes except *B. malayi* and *M. perstans*, humans are the only definitive host. Most of the filariases require prolonged exposure for disease to manifest and are therefore uncommon in short-term travelers to endemic areas.

CLINICAL MANIFESTATIONS

Clinical manifestations of infection are proportional to the worm burden harbored by an individual, with relatively light infections commonly being asymptomatic. For several of the filariases, the host inflammatory response to infection becomes apparent only when the death of the adult worms or microfilariae triggers exposure to filarial antigens that were previously hidden from the immune system or the release of bacterial endosymbionts of the genus *Wolbachia* that live inside several of the filariae. *Wolbachia* are of the order Rickettsiales and are found in the hypodermis of adult worms and in oocysts, embryos, and microfilariae; they play a critical role in worm viability and fertility.

DIAGNOSIS

Diagnosis of filarial infections often is based on the microscopic examination of blood or skin specimens for characteristic microfilariae (see Table 327-3). PCR assays developed by several research laboratories are more sensitive than traditional techniques, but none are yet commercially available. Microfilariae of the different filarial species measure between 170 and 320 μm in length and can be distinguished based on the tissue source of the specimen, the presence or absence of a sheath, and the arrangement of nuclei in the tail. Serology is not useful in endemic areas because a positive result does not distinguish between previous and current infection, and there is considerable antigenic cross-reactivity between the filariae and other nematodes. Detection of antifilarial antibodies may, however, be useful in returned long-term travelers or expatriates who are not originally from endemic areas.

TREATMENT

Diethylcarbamazine, ivermectin, and albendazole are the principal antifilarial drugs, although they have varying efficacies against the different filarial species (see Table 327-2). Diethylcarbamazine is macrofilaricidal (active against the adult worm) for *W. bancrofti*, *Brugia* species, and *L. loa*, although prolonged or repeated courses are required for this effect. More commonly, the goal is to suppress microfilaria production by female adult worms using single doses of antifilarial drugs administered alone or in combination annually or biannually. Reduction of microfilariae in the blood or skin can in some cases ameliorate symptoms or prevent progression of disease as well as interrupt transmission. Furthermore, targeting the *Wolbachia* endosymbionts of some filarial species with extended courses of doxycycline can be macrofilaricidal and has been incorporated into first-line treatment recommendations.

PROGNOSIS

Although not usually fatal, infection can result in considerable disability and disfigurement, such as irreversible limb lymphedema (*W. bancrofti* and *B. malayi*) or blindness (*O. volvulus*).

LYMPHATIC FILARISIS

DEFINITION

The three principal etiologic agents of lymphatic filariasis (*W. bancrofti, B. malayi*, and *B. timori*) are transmitted to humans through the bite of an infected mosquito.

EPIDEMIOLOGY

An estimated 50 million people are affected by lymphatic filariasis worldwide; over 90% of cases are caused by *W. bancrofti*, whereas less than 4 million are

TABLE 327-3 FILARIAL PARASITES OF HUMANS

			MICROFILARIAE		
SPECIES	**DISTRIBUTION**	**VECTOR**	**PRIMARY LOCATION**	**PERIODICITY**	**PRESENCE OF SHEATH**
Wuchereria bancrofti	Tropics worldwide	Mosquitoes	Blood	Nocturnal, subperiodic	+
Brugia malayi	India, Southeast Asia	Mosquitoes	Blood	Nocturnal, subperiodic	+
Brugia timori	Indonesia	Mosquitoes	Blood	Nocturnal	+
Onchocerca volvulus	Africa, South America	*Simulium* blackflies	Skin, eye	None or minimal	–
Loa loa	West and Central Africa	*Chrysops* flies	Blood	Diurnal	+
Mansonella perstans	Africa, South America, Caribbean	Midges	Blood	None	–
Mansonella ozzardi	Central and South America, Caribbean	Midges, *Simulium* blackflies	Blood	None	–
Mansonella streptocerca	West and Central Africa	Midges	Skin	None	–

due to *B. malayi*.[12] *B. timori* is of minor importance, being restricted to southeastern Indonesia. *W. bancrofti* is widely distributed in the tropics, especially in Southeast Asia, the Indian subcontinent, Africa, South America, the Caribbean, and the South Pacific. In Europe and North America, cases are seen in returning long-term travelers and in migrants.[13] The major vectors of bancroftian filariasis are *Culex* mosquitoes in urban areas, anopheline mosquitoes in rural areas of Africa, and *Aedes* species in the Pacific.

Humans are the only definitive host for *W. bancrofti*. *B. malayi*, however, can be zoonotic, with both monkey and feline species serving as reservoir hosts. Brugian filariasis is found primarily in India, Malaysia, and other areas in Southeast Asia.

PATHOBIOLOGY

Microfilariae deposited at the mosquito bite wound subsequently migrate through the subcutaneous tissue to the lymphatic system, where adult worms develop after approximately 4 to 12 months. The worms reside coiled in lymph nodes but may extend into afferent lymph vessels and surrounding subcutaneous tissue. The lymphatics of the lower and upper extremities and male genitalia are commonly affected. After mating, female worms, which measure between 4 and 10 cm in length and are twice the length of males, release more than 10,000 microfilariae a day that migrate into the blood stream, where they may be ingested by biting mosquitos. For most lymphatic filarial species, microfilariae appear in the peripheral blood only at night, when mosquito vectors are most likely to bite. Adult filariae live between 5 and 8 years within the host, although infections persisting for decades have been reported.

The pathology of filarial infections is primarily due to obstruction of lymphatic circulation resulting from damage induced by adult worms, specifically a localized inflammatory lymphangitis. This inflammatory response is triggered by release of antigens from dead or dying worms, although evidence suggests that it can also be induced by living worms and by excreted or secreted *Wolbachia* antigens. Inflammatory damage is often exacerbated by secondary bacterial and fungal infections.

The initial inflammatory response leads to endothelial and connective tissue proliferation and vessel dilation, which impairs normal lymphatic function and results in lymphedema that is initially reversible. However, worm death results in a granulomatous reaction to released worm and *Wolbachia* antigens. The infiltration of giant cells as well as plasma cells, eosinophils, and neutrophils can completely occlude the lumen of the lymphatic vessel. Over time, progressive fibrosis and obstruction of lymph circulation result in irreversible edema. Although recanalization and collateralization of lymph vessels may occur, lymphatic function remains compromised.

CLINICAL MANIFESTATIONS

The clinical manifestations of lymphatic filariasis range from asymptomatic infection to severe chronic lymphatic obstruction accompanied by lymphedema and enlargement of the affected limb or body part (referred to as elephantiasis). Other common clinical outcomes include acute episodic lymphadenitis (also called filarial fever) and tropical pulmonary eosinophilia, usually in younger individuals. Most infected individuals living in endemic regions are clinically asymptomatic, although microfilariae can be observed in their blood. Despite the absence of a significant inflammatory response, ultrasound examination may reveal lymphatic dilation that precedes the onset of clinically apparent disease.

For unknown reasons, newly exposed individuals may develop acute inflammatory reactions that can rapidly progress to chronic or irreversible changes compared with those born in endemic areas. Severe episodes of lymphadenitis, often with genital involvement, may lead to the relatively rapid development of lymphedema and elephantiasis within a year of arrival. Findings usually resolve quickly if the individual promptly leaves the endemic area. Microfilariae are usually not detected in these patients.

Acute Lymphadenitis

Acute episodes of retrograde lymphadenitis occur most commonly in adolescents in endemic areas, often in response to dying adult worms. Painful enlargement of an affected lymph node, most commonly inguinal, with accompanying erythema of the overlying skin precedes the onset of lymphangitis and is accompanied by fever and chills. Episodes usually persist for about a week, frequently recur, and can be incapacitating. Defervescence is abrupt and associated with desquamation of the overlying skin. In men, inguinal lymphadenitis can be complicated by epididymitis and orchitis. Patients with filarial fevers may be microfilaremic but often are not.

Elephantiasis

Repeated episodes of lymphadenitis eventually lead to dilation of the lymphatic vessels, thereby resulting in chronic lymphedema over the course of months to years

FIGURE 327-5. Elephantiasis, or chronic lymphedema, due to infection with *Wuchereria bancrofti*. (Courtesy of the Centers for Disease Control and Prevention.)

(Fig. 327-5). The extremities, breasts, and genitalia are most commonly affected, although *B. malayi* infection usually involves only the lower parts of the legs. The edema is initially pitting in nature, but the subcutaneous tissue eventually loses its elasticity, thereby resulting in woody edema with thickening of subcutaneous tissue and hyperkeratosis. Secondary bacterial or fungal infection is common.

In bancroftian filariasis, hydrocele is a common manifestation of chronic filariasis in men and can occasionally become massive and debilitating. Lymphedema of the vulva is sometimes but uncommonly seen in women. Involvement of the retroperitoneal lymphatics can lead to their rupture to produce intermittent chyluria or chylocele.

Tropical Pulmonary Eosinophilia

Tropical pulmonary eosinophilia (Chapter 156) develops in a small minority of individuals with filarial infections. The syndrome is most commonly seen in young men living in southern India, although it also occurs in Pakistan, Sri Lanka, and Southeast Asia. Clinical findings include nocturnal paroxysmal cough, wheeze, and low-grade fever that is accompanied by eosinophilia. Levels of total IgE and antifilarial antibodies are typically high. Chest radiographs may show diffuse interstitial infiltrates or mottled opacities. Without treatment, chronic restrictive lung disease may develop.

DIAGNOSIS

PCR is highly sensitive for detecting filarial antigens in blood, but these tests are currently available only as research tools and not for routine clinical diagnosis. As a result, diagnosis usually relies on microscopic examination of a Giemsa-stained blood smear for microfilariae. Although thick blood smears are relatively insensitive, except in cases of high microfilaremia, concentration or filtering techniques can increase diagnostic yield. Characteristic microfilariae are 250 to 320 μm in length. Collection of blood should be timed according to the known periodicity of the microfilariae.

A rapid immunochromatographic card test is available to detect *W. bancrofti* antigen (there is no equivalent test for *Brugia* infections) and has the advantage of not requiring nocturnal collection of blood because it detects circulating antigen of the adult worm and not microfilariae. Serologic detection of antifilarial antibodies is of limited value because of extensive antigenic cross-reactivity with other nematodes. Furthermore, actively infected individuals cannot be distinguished from those previously infected or merely exposed but not infected. Ultrasound examination of the lymphatic vessels of the spermatic cord of men can be used to visualize the "filarial dance sign," which is pathognomonic for a nest of filarial parasites.

Individuals with elephantiasis may be amicrofilaremic. Diagnosis therefore depends on a compatible clinical history and physical examination in the context of the appropriate epidemiology, and it may be supported by a positive antigen test, PCR (if available) or, in men, by a suggestive scrotal ultrasonogram. It should be distinguished from podoconiosis, which is a tropical lymphedema that results from long-term barefoot exposure to red-clay soil derived from volcanic rock and that may be a T-cell–mediated inflammatory disease.

TREATMENT

Management of lymphatic filariasis differs according to whether the aim is to control or cure the disease in an individual patient. In endemic areas, annual mass drug administration with a combination of two or three[A8,A9] antifilarial drugs can reduce transmission by decreasing the number of microfilariae that are in the blood

and available to biting mosquitoes. These programs use different combinations of single-dose diethylcarbamazine (6 mg/kg), ivermectin (200 µg/kg), and albendazole (400 mg), administered at least annually. The World Health Organization recommends that all three drugs be co-administered in regions where onchocerciasis and *L. loa* are not endemic, ivermectin plus albendazole in areas where onchocerciasis is also endemic, and albendazole alone in regions with loiasis.

All individuals with active infection by a lymphatic filarial parasite, whether symptomatic or asymptomatic, should be treated with an antifilarial medication (see Table 327-2). The treatment of choice is diethylcarbamazine (6 mg/kg given once). In the United States, diethylcarbamazine is available only through the Centers for Disease Control and Prevention (CDC) drug service (http://www.cdc.gov/laboratory/drugservice/formulary.html).

Diethylcarbamazine is both microfilaricidal and partially macrofilaricidal. In individuals who will not be returning to endemic areas, repeated treatments with diethylcarbamazine every 6 to 12 months are often attempted to kill the adult worms instead of just reducing the levels of microfilariae in the blood. Although the adult worm burden is reduced in most treated individuals, all parasites are eliminated in less than 25%. In men with live adult worms visible by ultrasound in the scrotal lymphatics, serial studies may be performed to monitor the effects of therapy.

Unfortunately, lymphedema due to lymphatic filariasis is usually not reversible with diethylcarbamazine treatment, except in the very early stages. Nevertheless, the chronic sequelae of lymphatic filariasis can be limited by preventing secondary bacterial and fungal infection through meticulous hygiene and prompt treatment of suspected infections with antimicrobials. Limb elevation, physiotherapy, and use of elastic stockings may slow the worsening of lymphedema. Surgery is usually not indicated except for cases of hydrocele.

Interestingly, treatment directed against the *Wolbachia* endosymbiont is effective for killing adult *W. bancrofti* and *Brugia* worms. Doxycycline 200 mg daily for 6 weeks reduces female worm fertility with a resulting suppression of microfilaremia for up to a year and reduces the number of live adult worms. This treatment course may also prevent progression of early-stage lymphedema.[14] Given the duration of treatment, these regimens are not ideal for disease control programs in endemic countries.

Diethylcarbamazine is very effective in the treatment of tropical pulmonary eosinophilia. Treatment with 6 mg/kg/day for 14 to 21 days results in resolution of symptoms within a week, although relapse may occur even after an interval of years.

See also Chapter 315.

PREVENTION

Annual mass treatment with single doses of one to three antifilarial drugs (see Treatment) can significantly reduce the prevalence of infection within a community. In some areas, diethylcarbamazine-fortified table salt has been used to reduce the levels of microfilaremia in affected communities to interrupt transmission. Vector control through use of insecticide-treated bed nets and residual indoor spraying of insecticides may have some efficacy.

PROGNOSIS

Even when clinically asymptomatic, most individuals with microfilaremia have evidence of subclinical disease, for which early treatment can forestall additional lymphatic damage. Unfortunately, once chronic lymphedema is established, it is not usually reversible with diethylcarbamazine treatment, although progression can be limited by supportive measures such as hygiene and prompt treatment of secondary bacterial or fungal infections. Drainage of hydroceles provides temporary relief, but fluid accumulation usually recurs in the absence of surgery or drug treatment.

ONCHOCERCIASIS

DEFINITION

Onchocerciasis, or river blindness, caused by the nematode *Onchocerca volvulus*, is transmitted to humans by *Simulium* blackflies. Infective microfilariae develop into male and female adult worms over a period of several months and live for 9 to 14 years coiled within subcutaneous fibrous nodules (onchocercomas). Adult females measure between 20 and 70 cm in length and remain confined to the nodules; males are only 3 to 5 cm long and freely migrate through the subcutaneous tissues between nodules to inseminate females. Each day, mature female worms produce up to 1500 microfilariae, which leave the nodule to migrate primarily through the skin and ocular tissues. Microfilariae live within the host for 12 to 18 months.

EPIDEMIOLOGY

Onchocerciasis is endemic in equatorial Africa, with small foci in Yemen and an area on the border between Brazil and Venezuela. Approximately 20 million people are estimated to be infected, and 1 million have vision loss due to this parasite. More than 99% of cases occur in sub-Saharan Africa, with Nigeria being the most highly endemic country. Because *Simulium* blackflies require fast-flowing, well-oxygenated water for egg laying and reproduction, cases are concentrated around streams and rivers, often in the most fertile farming areas.

PATHOBIOLOGY

The pathologic changes of onchocerciasis are primarily due to an inflammatory reaction to microfilariae, mostly in the skin, eyes, and lymph nodes. Adult worms contained in nodules are relatively isolated from the host immune response. Tissue damage results when dying microfilariae precipitate a cell-mediated immune response, which becomes more pronounced as infection persists. The degree of tissue damage is directly related to the intensity of infection as well as the magnitude of the host response. Sclerosing keratitis, which is the major cause of vision loss, results from a helper T-cell type 2 (T_H2)–driven inflammatory reaction to dying intraocular microfilariae. With time, neovascularization and scarring of the cornea lead to corneal opacification and eventual blindness. In the skin, similar immune responses result in pruritus and angioedema. Ongoing low-grade inflammation in the skin can eventually lead to loss of elasticity and atrophy. Chronic inflammatory changes and fibrosis are also seen in lymph nodes.

As with the nematodes responsible for lymphatic filariasis, *O. volvulus* adult worms contain endosymbiotic *Wolbachia* bacteria that are obligatory for the development, survival, and fertility of these worms. Pro-inflammatory *Wolbachia* proteins released by dying microfilariae may be responsible for a significant amount of the immunopathology associated with onchocerciasis. For example, *Wolbachia* antigens interact with the innate immune system through a toll-like receptor 2–mediated mechanism.

CLINICAL MANIFESTATIONS

Onchodermatitis

Onchocerciasis commonly presents with a diffuse papular dermatitis that is intensely pruritic. In heavily infected individuals, the pruritus can be intractable and lead to scratching and excoriation to the point of bleeding and even suicide. Hypersensitivity reactions, scabies, insect bites, and atopic or contact dermatitis should be considered in the differential diagnosis of the acute papular dermatitis seen with onchocerciasis. The skin of affected areas becomes edematous and thickened, loses its elasticity, and takes on an orange-peel texture. A lichenified dermatitis (referred to as sowda) may occur; it consists of an intensely pruritic eruption limited to one extremity, usually a leg, with hyperpigmented papules and plaques accompanied by edema of the entire limb. Over time, the skin atrophies, and fine wrinkles appear, especially over the buttocks. Pruritus is uncommon at this point. Areas of depigmentation may occur, most commonly over the shins, a phenomenon called leopard skin.

Subcutaneous Nodules

Subcutaneous onchocercomas containing adult worms are most often palpable over bony prominences. In Africa, the nodules are often found over the hips and lower limbs; in South America, they are usually located on the head and upper part of the body. Nodules measure between 0.5 and 3 cm in diameter and are freely mobile. In lightly infected individuals, such as expatriates, palpable nodules are usually not present.

Ocular Lesions

Initial ocular involvement is characterized by conjunctivitis, excess tearing, and photophobia in response to dying microfilariae. At this point in the course of disease, punctate keratitis or snowflake corneal opacities are present. Over 20 to 30 years of chronic infection, the disease progresses to sclerosing keratitis, neovascularization, and corneal opacification. The anterior chamber of the eye may also be involved, with iritis, iridocyclitis, and secondary glaucoma. Posterior ocular disease can manifest as chorioretinitis, optic neuritis, and optic atrophy.

Neurologic Manifestations

Onchocerciasis has been linked epidemiologically to epilepsy, intellectual disability, and failure to thrive. This link has been suggested by evidence that these syndromes have declined markedly after the elimination of onchocerciasis in hyperendemic areas, such as western Uganda.[15]

Lymphadenopathy

Lymphadenopathy is frequently found in the inguinal area in Africa and in the head and neck in South America. Advanced inguinal lymphadenopathy can result in the so-called hanging groin, with elongated atrophic skin containing nontender and fibrotic lymph nodes.

DIAGNOSIS

Definitive diagnosis has traditionally been made by observing unsheathed motile microfilariae, measuring 200 to 300 µm in length, that are released from superficial

skin snips. To collect a skin snip, a thin piece of skin overlying a bony prominence that has been tented up with a needle is sliced with a scalpel blade, or a corneal-scleral punch instrument is used to obtain a small piece of skin. Avoidance of blood contamination is critical to avoid confusion with blood-borne microfilariae in cases in which patients are coinfected with other filariases. Typically, six snips are taken, one from over each scapula, iliac crest, and lateral aspect of each calf, and then incubated for up to 24 hours in warm physiologic saline and examined microscopically for motile microfilariae. PCR amplification of filarial DNA directly from skin snips is far more sensitive than direct visualization but is not widely available. With ocular disease, free microfilariae may be visible by slit lamp examination in the anterior chamber or aqueous humor.

Subcutaneous nodules can be sampled or examined by ultrasound to demonstrate the presence of adult worms. Serologic tests are usually positive for antifilarial antibodies but are not specific because of considerable antigenic cross-reactivity with other nematodes. Eosinophilia is a common but inconsistent finding.

TREATMENT

The macrocytic lactones ivermectin or moxidectin, in combination with doxycycline, are the treatments of choice for onchocerciasis (see Table 327-2). Administration of a single dose of ivermectin (150 µg/kg) or moxidectin (8 mg [age > 12 yr]) is effective in ameliorating ocular and dermatologic disease by destroying microfilariae and suppressing their release from female worms.[A10] However, since macrocyclic lactones are not active against adult worms, monotherapy with them must be repeated every 6 to 12 months, probably for at least 10 years in patients without further exposure. For unknown reasons, pruritus in lightly infected expatriates may require more aggressive and frequent treatment for the first 2 years. Within 24 hours of treatment, fever and pruritus may occur in reaction to the dying microfilariae or released *Wolbachia* antigens, especially in patients with high pretreatment levels of microfilariae.

Doxycycline 200 mg/day administered for 6 weeks, preceded by and followed by a single dose of ivermectin or moxidectin, depletes *Wolbachia* endosymbionts from adult worms, thereby resulting in a significant macrofilaricidal effect and suppression of embryogenesis and microfilaria production for up to 18 months in the remaining adult worms.[A11] This regimen is recommended if patients with onchocerciasis have departed from an endemic area and will not be re-exposed. Following initial treatment, ivermectin or moxidectin should be given every 3 to 6 months until patients are asymptomatic and then repeated annually for at least 3 years.

Ivermectin and moxidectin should be used with caution in areas where *L. loa* (see later) is coendemic because it may precipitate severe reactions, including encephalopathy in patients with high levels of microfilaremia. Diethylcarbamazine should never be used to treat onchocerciasis because of frequent serious reactions to dying microfilariae, ranging from urticaria and angioedema to hypotension and death. Although the drug suramin (available from the CDC drug service) is active against adult *O. volvulus* worms, it is used only in rare situations because of its toxicity. Nodulectomy successfully resolves the infection in some cases.

See also Chapter 315.

PREVENTION

Regular mass administration of ivermectin (150 µg/kg as a single dose) to entire communities in endemic regions forms the core of the global eradication strategy for onchocerciasis. Implementation of this program has been made easier because the drug is donated by the manufacturer. In addition to benefiting infected individuals, mass drug administration reduces the number of microfilariae available to vectors and thus interrupts transmission. For travelers to endemic areas, use of insect repellent is beneficial.

PROGNOSIS

Vision loss caused by *O. volvulus* results in significant morbidity, long-term disability, and reduced economic productivity. When untreated, onchocerciasis has been associated with a reduced life expectancy of at least 10 years compared with uninfected individuals in the same area, an effect that appears to be independent of the blindness that develops. Treatment with repeated doses of a macrocytic lactone significantly reduces the likelihood of these outcomes.

LOIASIS

DEFINITION

Loiasis is caused by infection with the filarial nematode *Loa loa*, also known as the African eye worm. *L. loa* are transmitted by flies of the genus *Chrysops* during a blood meal. Adult worms develop during a period of 1 to 4 years and can live for up to 17 years. They migrate freely in the subcutaneous tissue, including the subconjunctiva or sclera of the eye. Adult females measure between 40 and 70 mm in length; males are shorter, measuring between 25 and 35 mm. After mating, females release microfilariae into the blood. *L. loa* microfilariae exhibit a diurnal periodicity coinciding with the feeding habits of *Chrysops*, with microfilaremia peaking around midday.

EPIDEMIOLOGY

Loiasis is endemic in the rainforest regions of Central and West Africa, with the highest prevalence in Gabon, Cameroon, the Democratic Republic of the Congo, Nigeria, and the Central African Republic.[16] Symptomatic loiasis can develop after a shorter period of exposure compared with other filarial infections, so it can be seen in returning travelers or expatriates who have spent extended periods in Africa.

PATHOBIOLOGY

Neither adult *L. loa* worms nor microfilariae have any direct pathologic effects. In a subset of infected individuals, a hypersensitivity response, termed a *Calabar swelling*, develops to secretions from adult worms or released microfilariae, thereby resulting in recurrent localized angioedema that often precedes the migrating worm. These patients have high serum levels of IgE antibodies and eosinophilia. Unlike other filariae, *L. loa* does not contain *Wolbachia* endosymbionts.

CLINICAL MANIFESTATIONS

Most individuals with loiasis are asymptomatic despite being microfilaremic. Recurrent Calabar swellings and eyeworm are the most common findings.[17] Calabar swellings measure 5 to 20 cm in diameter, typically occur on the extremities and the face, and persist for a few days. The onset is often preceded by pruritus and pain. On occasion, adult worms may migrate across the subconjunctiva or sclera of the eye, thereby causing severe pain and inflammation (Fig. 327-6). Rare complications of infection include nephropathy and encephalitis, which usually develop in patients with high levels of microfilariae after receiving diethylcarbamazine or ivermectin treatment for other filarial infections. Endomyocardial fibrosis, resulting from eosinophilic infiltration of the myocardium, has been reported in association with loiasis.

DIAGNOSIS

Diagnosis depends on microscopic examination of a Giemsa-stained blood film for characteristic sheathed microfilariae. PCR testing is performed in research laboratories but is not generally available or FDA-approved. Blood should be collected between 10 AM and 2 PM because of the diurnal periodicity of the microfilariae; if someone has traveled from an endemic area, collection should be performed in relation to the time zone where the infectious bite occurred. Because individuals who are not native to endemic areas are usually not microfilaremic, diagnosis relies on a compatible history, clinical findings, peripheral eosinophilia, and elevated antifilarial antibody levels. Adult worms can sometimes be surgically removed while migrating across the eye or through subcutaneous tissues. Calabar swellings must be distinguished from onchocercomas and other causes of angioedema.

TREATMENT

Diethylcarbamazine (8 to 10 mg/kg/day for 21 days) is active against both adult *L. loa* worms and microfilariae (see Table 327-2). Treatment is usually increased from a dose of 50 mg/day on the first day to the full dose on the fourth day to minimize the likelihood of treatment-associated complications, the most

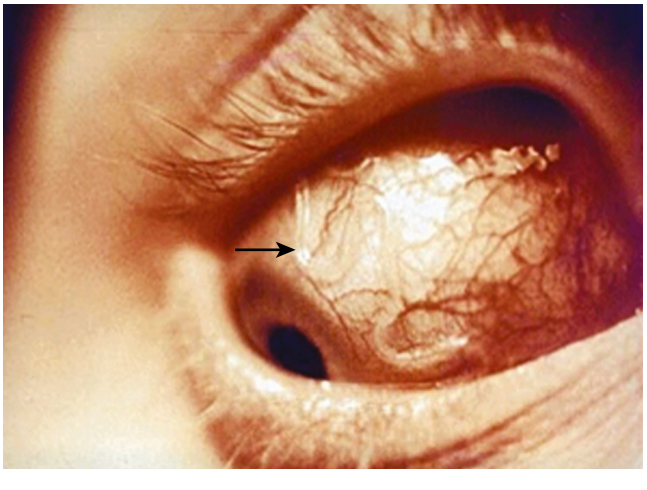

FIGURE 327-6. Adult *Loa loa* worm migrating across the eye *(arrow)*.

serious of which are glomerulonephritis and a potentially fatal encephalopathy. Treatment-associated complications, which are more common with high pretreatment microfilarial levels (>2500 microfilaria/ml), result from host allergic reactions to dying microfilariae. Corticosteroids (e.g., prednisone 40 mg daily or the equivalent for 4 to 5 days) may prevent allergic side effects. Alternatively, apheresis can be used to remove circulating microfilariae before initiation of diethylcarbamazine. Albendazole (200 mg orally twice a day for 3 weeks), which is microfilaricidal but has no activity against adult worms, can be used to reduce high-level microfilaria before treatment with diethylcarbamazine. The same albendazole regimen has shown some success in patients who have failed two rounds of diethylcarbamazine. Repeated courses of diethylcarbamazine may be necessary in about 50% of patients before clinical manifestations completely resolve. Persistent or increasing eosinophilia or levels of antifilarial antibodies 6 months after treatment should also prompt re-evaluation for repeated treatment. Adult worms in the eye may be surgically removed.

Ivermectin is microfilaricidal but has no macrofilaricidal effect and may cause toxic encephalopathy in individuals with high-level microfilaria. In areas where onchocerciasis is co-endemic, this infection should be excluded or treated before initiation of diethylcarbamazine to prevent toxicity from dying *O. volvulus* microfilariae.

See also Chapter 315.

PREVENTION

Weekly chemoprophylaxis with diethylcarbamazine administered as a 300-mg dose is effective in preventing loiasis in long-term residents of endemic areas.

PROGNOSIS

Although repeated courses of diethylcarbamazine are required in about 50% of patients before complete resolution of clinical manifestations, immunologic perturbations (e.g., eosinophilia, antifilarial antibody levels) nearly always resolve within 1 year of definitive treatment.[18]

LESS COMMON FILARIAL INFECTIONS

Mansonella perstans

M. perstans infection occurs throughout West and Central Africa, in northeastern South America, and in parts of the Caribbean. Microfilariae are transmitted by *Culicoides* midges and develop into adult worms that live in serous body cavities, such as the pleural, pericardial, and peritoneal spaces, as well as in mesenteric and retroperitoneal tissues. Most infections are asymptomatic, although painless conjunctival nodules with eyelid edema have been reported. Transient angioedema and Calabar-like swellings, fever, headache, arthralgias, and neurologic manifestations may also occur. Microfilariae do not exhibit periodicity and can be observed on stained blood films. Eosinophilia is common. *M. perstans* harbors *Wolbachia* endosymbionts, and treatment with doxycycline 200 mg/day for 6 weeks is highly effective in suppressing microfilaremia for up to 3 years, thereby suggesting that the treatment is macrofilaricidal.

Mansonella ozzardi

Infections with *M. ozzardi* occur in Central and South America and parts of the Caribbean, especially Haiti. Vectors include *Simulium* blackflies and midges. Adult worms locate to the peritoneal and thoracic cavities or the lymphatics; microfilariae circulate in the blood without periodicity. Infection usually results in asymptomatic eosinophilia, although corneal lesions and arthritis have been reported. Allergic symptoms such as urticaria and lymphadenopathy may occur in response to dying worms. *M. ozzardi* microfilariae are highly susceptible to ivermectin, and administration of a single dose of 200 µg/kg may provide long-term suppression of microfilaremia and improvement of symptoms.[19] Neither diethylcarbamazine nor the benzimidazoles are effective.

Mansonella streptocerca

M. streptocerca is endemic in the tropical forest zone of West and Central Africa and is transmitted by biting midges. Similar to *O. volvulus*, both adult worms and microfilariae reside in the subcutaneous tissues. In contrast to onchocerciasis, microfilariae do not invade the eye. Infection is usually asymptomatic, although a pruritic dermatitis with depigmentation similar to onchodermatitis can affect the trunk and upper extremities. Associated axillary or inguinal adenopathy is common. Microfilariae have characteristic hooked tails and can be visualized in skin snips. In areas where onchocerciasis is co-endemic, skin specimens must be stained to differentiate *M. streptocerca* from *O. volvulus*. Diethylcarbamazine, which is microfilaricidal and macrofilaricidal, is given as 6 mg/kg/day for 12 days. Ivermectin is not macrofilaricidal but is highly effective at eliminating microfilariae from the skin. It is likely that ivermectin-containing mass drug administration programs targeting lymphatic filariasis and onchocerciasis in Africa have significantly reduced this parasite's transmission.

ZOONOTIC FILARIAL INFECTIONS

Rare accidental filarial infections of humans with the dog heartworm *Dirofilaria immitis* occur worldwide. Transmitted by mosquitoes, *D. immitis* microfilariae cannot reach maturity in humans but embolize to the lung after dying in the right ventricle. Most infections are asymptomatic, but some people experience cough, chest pain, and hemoptysis consistent with lung infarction. Chest radiographs demonstrate typical coin lesions that may be mistaken for carcinoma. Other animal filariae, including *Dirofilaria repens* of dogs and *Dirofilaria tenuis* of raccoons, can infect humans and result in subcutaneous nodules that may be migratory. Eosinophilia and antifilarial antibodies are not usually present in zoonotic filarial infections. Surgical removal of lesions is both diagnostic and curative.

DRACUNCULIASIS

Dracunculiasis is a disfiguring disease caused by the nematode *Dracunculus medinensis*, or Guinea worm. Although previously found in the Indian subcontinent and Latin America, it is now endemic in only six countries in sub-Saharan Africa (Chad, Ethiopia, South Sudan, Angola, Mali, and Cameroon) due to concerted eradication efforts. In 2020, fewer than 30 cases were identified. Transmission to humans occurs through ingestion of copepods, tiny crustacean intermediate hosts that harbor infective larvae. Released larvae penetrate the intestinal wall and migrate to the subcutaneous tissues, where they develop into adult worms. After approximately a year, female worms induce vesicular skin lesions, usually on the lower extremities, that eventually ulcerate. On direct contact with fresh water, the female worm releases thousands of motile larvae that can then complete the transmission cycle by infecting copepods in the water. Adult worms measure up to a meter in length. Fever and allergic symptoms, including wheezing and urticaria, may precede rupture of the blister or occur upon attempted extraction of the worm. Secondary bacterial infection of the skin lesions is frequent. Although not commonly fatal, dracunculiasis can result in significant disability.

Traditionally, emerging worms are extracted by slowly winding a few centimeters of the parasite on a stick each day, taking care not to break it. Surgical removal can be attempted but may exacerbate allergic symptoms. There is no effective chemotherapy for this infection. Prevention efforts have been highly successful in interrupting transmission and have led to eradication of the parasite from many countries. Strategies include filtering of drinking water through finely woven cloth, education of infected individuals not to enter fresh water, treatment of water sources with larvicides, and provision of safe drinking water from wells.

328 ANTIVIRAL THERAPY (NON-HIV)

JOHN H. BEIGEL AND SHYAMASUNDARAN KOTTILIL

Although some viral infections are self-limited, others can cause significant morbidity and mortality. Effective therapy is available for many of these infections. This chapter reviews currently available antiviral agents for the treatment of infections caused by viruses other than human immunodeficiency virus (HIV). Not all agents discussed are licensed in all countries.

Currently available agents can be classified into those that inhibit viral replication at the cellular level or bind the virus (antivirals), those that modify the host antiviral response to infection (immunomodulators), and those that directly inactivate viral particles (microbicides/virucides). Antiviral agents can be classified based on their mechanism of action.[1] For example, nucleic acid analogues inhibit viral DNA or RNA synthesis by competing with endogenous nucleic acids and block the viral DNA polymerase or RNA transcriptases. By comparison, protease inhibitors prevent viral replication by binding to the enzymes that cleave viral protein precursors into active proteins.

Antiviral strategies that are not covered in this chapter include local destructive measures that destroy both host tissues and virus simultaneously, such as cryotherapy, laser, and podophyllin treatment of warts. Although effective, such measures are useful only for discrete or localized mucocutaneous infections.

ANTIVIRALS FOR HEPATITIS B VIRUS INFECTIONS

Acute hepatitis B virus (HBV) infection (Chapter 134) generally does not require antiviral treatment. Currently approved antivirals for chronic hepatitis B (Chapter 135) include six nucleic acid analogues (adefovir, entecavir, lamivudine, telbivudine, tenofovir disoproxil fumarate, and tenofovir alafenamide), as well as two immune modulators (interferon-alfa-2b and pegylated [PEG]-interferon-alfa-2a) (Tables 328-1 to 328-3).[2] Treatment may be initiated with any approved antiviral medications, but tenofovir, tenofovir alafenamide, entecavir, and PEG-interferon-alfa-2a are generally the preferred agents. Tenofovir or entecavir is preferred for patients with compensated cirrhosis (Chapter 139). The goal of antiviral treatment is to suppress HBV replication and reduce the progression of liver disease and its complications.

Patients with chronic hepatitis B (hepatitis B surface antigen [HBsAg]-positive for >6 months, detectable serum HBV DNA [>2000 IU/mL for hepatitis B e antigen (HBeAg)-negative patients, >20,000 IU/mL for HBeAg-positive patients, and >200,000 IU/mL for pregnant women], and an alanine aminotransferase level more than twice the normal level) should be evaluated for treatment. Patients with clinically decompensated hepatitis B (e.g., icterus or other signs) generally require antiviral treatment. Therapy in HBeAg-positive chronic hepatitis B should be continued until the patient has achieved HBeAg seroconversion and serum HBV DNA is undetectable, followed by at least 6 months of additional treatment after the appearance of anti-HBe. Therapy in HBeAg-negative chronic hepatitis B should continue for at least a year. Patients with decompensated cirrhosis or recurrent hepatitis B after liver transplantation should receive lifelong treatment.

TENOFOVIR DISOPROXIL FUMARATE

Tenofovir, a nucleotide analogue of adenosine monophosphate, was first approved for the treatment of HIV infection. Tenofovir disoproxil fumarate is an ester prodrug of tenofovir, with an effective tenofovir bioavailability of 25%. Administration following a high-fat meal increases the oral bioavailability.

Clinical Uses

Tenofovir is approved for the treatment of chronic hepatitis B in adults with evidence of active viral replication and either persistent elevations in serum aminotransferase levels or histologically active disease. Treatment with tenofovir is more effective than adefovir or entecavir for producing histologic improvement and viral suppression in patients with HBeAg-negative or HBeAg-positive chronic hepatitis B.[A1] Tenofovir also has demonstrated efficacy in patients with lamivudine-resistant hepatitis B.

TABLE 328-1 ANTIVIRALS FOR HEPATITIS VIRUS INFECTIONS

VIRAL INFECTION	DRUG	ROUTE	USUAL ADULT DOSAGE
Chronic hepatitis B	Tenofovir disoproxil fumarate	PO	300 mg/day
	Tenofovir alafenamide	PO	25 mg/day
	Entecavir		
	Naïve virus	PO	0.5 mg daily; optimal duration of therapy unknown
	Lamivudine-resistant virus	PO	1 mg daily; optimal duration of therapy unknown
	Interferon-alfa-2b	SQ	6 MU/m² (up to 10 MU) three times weekly for 16-24 wk
	PEG-interferon-alfa-2a	SQ	180 µg weekly for 48 wk
	Adefovir	PO	10 mg/day
	Lamivudine	PO	100 mg/day
	Telbivudine	PO	600 mg/day
Chronic hepatitis C	Ledipasvir/sofosbuvir	PO	90 mg/400 mg once daily for 8-24 wk
	Sofosbuvir/velpatasvir	PO	400 mg/100 mg/day for 12 wk
	Sofosbuvir/velpatasvir/voxilaprevir	PO	400 mg/100 mg/100 mg/day for 12-24 wk
	Sofosbuvir/glecaprevir/pibrentasvir	PO	400 mg/100 mg/40 mg once daily for 12-24 wk
	Daclatasvir/sofosbuvir	PO	60 mg/400 mg/day for 12-24 wk
	Grazoprevir/elbasvir	PO	100 mg/50 mg/day for 12-16 wk
	Glecaprevir/pibrentasvir	PO	300 mg/120 mg/day for 8-16 wk
	Daclatasvir/asunaprevir	PO	60 mg/400 mg/day for 24 wk
	Sofosbuvir	PO	400 mg once daily for 12-24 wk
	PEG-interferon-alfa-2a	SQ	180 µg weekly for 48 wk
	or PEG-interferon-alfa-2b	SQ	1.5 µg/kg weekly for 48 wk
	plus ribavirin	PO	800-1200 mg/day, depending on weight

PO = orally; SQ = subcutaneously.

Toxicity

Tenofovir is generally safe and well tolerated for up to 5 years. The most common side effects are nausea, diarrhea, vomiting, and anorexia. Lactic acidosis with hepatic steatosis has been reported, primarily when it is used in combination with other nucleoside analogues. Acute exacerbations of hepatitis B have been reported after discontinuation of tenofovir in patients who are coinfected with HIV and hepatitis B.

Antiviral Resistance

Mutations in hepatitis B polymerase that confer reduced susceptibility to tenofovir occur during prolonged use (>12 months). In vitro studies showed that adefovir-resistant hepatitis B mutations are associated with three- to five-fold decrease in response to tenofovir, though clinical implications are not known.

TENOFOVIR ALAFENAMIDE

Tenofovir alafenamide, which is a prodrug of tenofovir, is a successor of tenofovir disoproxil fumarate. Tenofovir alafenamide is converted intracellularly to tenofovir. Its active diphosphate metabolite is targeted at the RNA-dependent DNA polymerase of either hepatitis B or HIV. Tenofovir alafenamide is also licensed to treat hepatitis B infection. Tenofovir alafenamide accumulates

ABSTRACT

A number of antiviral agents are available for the treatment of viral infections other than human immunodeficiency virus (HIV). Acute hepatitis B virus (HBV) and hepatitis C virus (HCV) infection generally do not require antiviral treatment. The preferred regimens for chronic hepatitis B include tenofovir disoproxil fumarate, tenofovir alafenamide, entecavir, and PEG-interferon-alfa-2a. Several direct-acting antiviral agents are highly effective against all genotypes (1-6) of HCV. Acyclovir or valacyclovir are the preferred treatments of herpes simplex and varicella-zoster virus. Ganciclovir or valganciclovir are the preferred treatments of cytomegalovirus. Oseltamivir is the preferred treatment of influenza. In nonhospitalized adults, either the combination of nirmatrelvir boosted with ritonavir or monotherapy with molnupiravir can reduce the progression of COVID-19. For patients who are hospitalized with COVID-19, remdesivir improves time to recovery and reduces mortality, primarily in patients who are receiving oxygen therapy.

TABLE 328-3 SIGNIFICANT ADVERSE EFFECTS (U.S. FDA BLACK BOX WARNING)

DRUG	BLACK BOX SYNOPSIS
Adefovir	Severe acute exacerbations of hepatitis B may occur with cessation of therapy Nephrotoxicity may occur in patients at risk for renal dysfunction Lactic acidosis and severe hepatomegaly with steatosis
Entecavir	Severe acute exacerbation of hepatitis B may occur with cessation of therapy Lactic acidosis and severe hepatomegaly with steatosis
Grazoprevir/elbasvir	Hepatitis B virus reactivation in patients with HCV and HBV
Interferon-alfa	May cause or aggravate neuropsychiatric, autoimmune, ischemic, and infectious disorders
Lamivudine	Severe acute exacerbations of hepatitis B may occur with cessation of therapy Lactic acidosis and severe hepatomegaly with steatosis
Ledipasvir/sofosbuvir	Hepatitis B virus reactivation in patients with HCV and HBV
Voxilaprevir	Hepatic failure in patients with decompensated liver cirrhosis
Glecaprevir/pibrentasvir	Hepatic failure in patients with decompensated liver cirrhosis
Ribavirin	Monotherapy is not effective Hemolytic anemia Teratogenic and embryocidal
Sofosbuvir	Life-threatening bradycardia when administered with amiodarone Hepatic failure in patients with decompensated liver cirrhosis
Telbivudine	Severe acute exacerbation of hepatitis B may occur with cessation of therapy Lactic acidosis and severe hepatomegaly with steatosis
Tenofovir or tenofovir alafenamide	Severe acute exacerbations of hepatitis B may occur with cessation of therapy

HBV = hepatitis B virus; HCV = hepatitis C virus.

in lymphatic tissue and in the liver, and it enters cells more efficiently than tenofovir disoproxil fumarate. For these reasons, tenofovir alafenamide can be given at a lower dose, thereby resulting in lower plasma tenofovir levels and a much lower risk for kidney toxicity or bone density changes.

Clinical Uses

In clinical trials, tenofovir alafenamide was noninferior to tenofovir disoproxil fumarate in achieving HBV DNA levels below 29 IU/mL.[A2] Tenofovir alafenamide–treated patients had significantly smaller decreases in bone mineral density at the hip and spine in both HBeAg-positive and HBeAg-negative patients, and HBeAg-positive patients also had smaller mean increases in serum creatinine levels. Patients treated with tenofovir disoproxil fumarate for 96 weeks and then switched to tenofovir alafenamide had improvements in renal function and bone mineral density 24 weeks after switching.

Toxicity

Compared with tenofovir disoproxil fumarate, tenofovir alafenamide has less adverse effects on kidney (glomerular and tubular) function and bone mineral (spine, hip) density.

Antiviral Resistance

Tenofovir alafenamide leads to little or negligible emergence of drug resistance (to tenofovir). Clinical observations show a very low incidence of hepatitis B genotype resistance in treatment-naïve patients treated either with tenofovir alafenamide or tenofovir disoproxil fumarate. In patients treated with elvitegravir, cobicistat, and emtricitabine combined with either tenofovir alafenamide or tenofovir disoproxil fumarate, emergence of drug resistance did not exceed 1% for either HIV and hepatitis B.

ENTECAVIR

Entecavir, which is a deoxyguanosine nucleoside analogue with specific antiviral activity for hepadnaviruses, is more potent than lamivudine and retains some activity against lamivudine-resistant hepatitis B variants. It is well absorbed after oral administration, and its prolonged half-life (128 to 149 hours) allows once-daily dosing.

Clinical Uses

Entecavir is approved for the treatment of chronic hepatitis B in adults with evidence of active viral replication and either persistent elevations in serum aminotransferases or histologically active disease. Compared with lamivudine or telbivudine, entecavir is more efficacious in reducing hepatitis B DNA levels and normalizing serum aminotransferases, as well as in improving histologic abnormalities. Like tenofovir, entecavir can be used for lamivudine-resistant HBV infections, but higher doses and longer durations of therapy are needed.

Toxicity

Adverse effects reported during entecavir therapy include headache, fatigue, dizziness, nausea, abdominal pain, rhinitis, fever, diarrhea, cough, and myalgia. Lactic acidosis and severe hepatomegaly with steatosis have been reported.

Severe exacerbations of hepatitis B have been observed after cessation of therapy.

Antiviral Resistance

Virologic breakthrough can occur in up to 4% of patients but is usually not indicative of resistant virus. True entecavir resistance, which is caused by specific mutations in hepatitis B polymerase, is uncommon (1.2% after 5 years of treatment). In vitro studies show that entecavir-resistant mutations are susceptible to adefovir and tenofovir, but there are very few supportive clinical data.

INTERFERONS

Interferons are glycoprotein cytokines with a complex array of antiviral, immunomodulating, and antineoplastic properties. Interferons are currently classified as α, β, or γ. The natural sources of these classes in general are leukocytes, fibroblasts, and lymphocytes, but they now can be produced by recombinant DNA technology. Although the full mechanism of interferon's action is not defined, interferons generally induce synthesis of new cellular RNA and proteins that mediate antiviral effects through multiple different mechanisms.

Interferons generally must be administered daily or several times per week. However, the combination of interferon with polyethylene glycol to form PEG-interferon significantly prolongs absorption and provides higher, more sustained plasma levels that enable once-weekly administration.

Clinical Uses

In chronic active hepatitis B, treatment with interferon-alfa leads to loss of HBV DNA and biochemical and histologic improvement in about 25 to 40% of patients. Administration of PEG-interferon-alfa-2a or PEG-interferon-alfa-2b for 48 weeks converts about 30% of patients to seronegative status after 6 months of treatment. Whether combination therapy with interferons and antivirals confers an additional benefit compared with monotherapy for treating chronic hepatitis B is not known.

ADEFOVIR

Adefovir, an acyclic analogue of adenosine monophosphate, is administered orally as a prodrug, adefovir dipivoxil, which is rapidly converted enzymatically to adefovir in intestinal epithelium.

Clinical Uses

In chronic hepatitis B, prolonged administration of adefovir is effective in improving histologic abnormalities of the liver, decreasing HBV DNA levels, and normalizing biochemical markers (e.g., alanine aminotransferase) in patients with HBeAg-positive and HBeAg-negative chronic hepatitis B. Adefovir is a slightly weaker antiviral and therefore not considered first-line therapy, but it is useful for resistant viruses (effective against chronic hepatitis B resistant to lamivudine) and HIV/HBV coinfection (see later).

Toxicity

The major adverse effect is nephrotoxicity, which is manifested by increased serum creatinine levels and sometimes hypophosphatemia, both of which are usually reversible with discontinuation of the drug. Common side effects include asthenia, headache, nausea, vomiting, and diarrhea. In addition, severe exacerbations of hepatitis B have been observed after cessation of therapy.

Antiviral Resistance

Adefovir resistance due to point mutations in HBV polymerase develops in about 6% of patients after 3 years of therapy. Lamivudine generally retains activity against adefovir-resistant variants.

LAMIVUDINE

Lamivudine is a deoxycytidine nucleoside analogue active against retroviruses and hepadnaviruses. The triphosphate inhibits HBV polymerase, and its incorporation into viral DNA results in termination of the DNA chain.

Clinical Uses

Lamivudine suppresses hepatitis B viral replication, improves histologic abnormalities of the liver, reduces progression of fibrosis, and decreases the risk for late complications. Monotherapy with lamivudine appears to be inferior to the newer antivirals, as well as monotherapy with interferon, for sustained control of HBV replication. Combination therapy with lamivudine and interferon has shown inconsistent benefit compared with either drug alone. The dosing for HBV is lower than for HIV.

Toxicity

Adverse effects of lamivudine include diarrhea, headache, and elevated liver enzymes. Severe post-treatment exacerbations of hepatitis B, including fatalities, have occurred after discontinuation of lamivudine, especially in patients who are coinfected with HBV and HIV.

Antiviral Resistance

Lamivudine resistance caused by mutations in HBV polymerase is common during prolonged treatment of hepatitis B and emerges in about 20% of treated patients annually. Resistance is associated with increases in viral replication and aminotransferases.

TELBIVUDINE

Telbivudine is a synthetic thymidine nucleoside analogue with activity against HBV, including some lamivudine-resistant variants. The triphosphate form competitively inhibits the HBV DNA polymerase (reverse transcriptase).

Clinical Uses

In comparative trials against lamivudine or adefovir, telbivudine demonstrated greater virologic response at week 52 (60 vs. 40% of subjects had HBV DNA negative by polymerase chain reaction analysis). The development of resistance with telbivudine is up to 5% after 1 year and 25% after 2 years. Telbivudine-resistant viruses are cross-resistant with lamivudine. Owing to the high development of resistance and cross-resistance, telbivudine is not considered a first-line treatment for hepatitis B.

Toxicity

Common side effects include headache, nausea, and vomiting. Severe acute exacerbations of hepatitis B have been reported in patients who have discontinued anti-HBV therapy. Myopathy, manifested by muscle aches or weakness with increased serum creatine kinase levels, has rarely been reported.

Special Considerations—HIV/HBV Coinfection

Lamivudine, entecavir, tenofovir, and tenofovir alafenamide have activity against both HIV and HBV. Monotherapy treatment of HBV with these agents should not be used in HIV coinfected patients, owing to the development of HIV resistance. Emtricitabine is licensed only for the treatment of HIV but is also weakly active against HBV. Withdrawal of this medication, like withdrawal of tenofovir or lamivudine, may cause acute, sometimes fulminant, exacerbations of hepatitis B in HIV/HBV coinfected patients.

If concurrent treatment of hepatitis B and HIV is warranted, tenofovir plus emtricitabine, tenofovir plus lamivudine, or tenofovir alafenamide plus emtricitabine should be considered as the nucleoside backbone of a fully suppressive antiretroviral regimen. If tenofovir or tenofovir alafenamide cannot be used, entecavir is an alternative as part of an antiretroviral regimen. In coinfected patients who require treatment for HBV but not HIV or who are already well controlled on anti-HIV viral therapy but now need hepatitis B treatment, PEG-interferon-alfa-2a monotherapy should be considered. If the antiretroviral regimen must be changed owing to HIV virologic failure and the HBV is adequately suppressed, antiviral drugs active against HBV should be continued for HBV treatment.

ANTIVIRALS FOR HEPATITIS C VIRUS INFECTIONS

Treatment of acute hepatitis C remains symptomatic, and antiviral therapy generally is not indicated. For chronic hepatitis C (Chapter 135), however, the goal of therapy is sustained virologic response (absence of hepatitis C virus [HCV] RNA for at least 12 weeks after completion of therapy) to prevent the morbidity and mortality associated with liver disease and long-term complications, such as hepatocellular carcinoma, liver failure, transplantation, and death. Treatment has been shown to decrease liver inflammation and cirrhosis as well as reduce the risk for hepatocellular carcinoma.

Although some specific drugs are more effective for specific HCV genotypes, current therapy is based on pangenotypic oral combinations (Table 135-5), guided by whether or not patients have cirrhosis.[A3] Interferon-free regimens are preferred over interferon-based regimens (see Table 135-5 in Chapter 135 and Tables 328-1 to 328-3).[3] Direct-acting antiviral agents are highly active oral medications available to treat all genotypes of HCV. Sofosbuvir/velpatasvir glecaprevir/pibrentasvir with or without sofosbuvir, and sofosbuvir/daclatasvir are considered primary regimens for HCV regardless of genotype. Retreatment after failure of the initial regimen generally requires expert consultation.

LEDIPASVIR/SOFOSBUVIR

Ledipasvir is an HCV NS5A inhibitor. Sofosbuvir is a nucleotide prodrug that, when triphosphorylated, inhibits HCV NS5B, an RNA-dependent RNA polymerase. Both NS5A and NS5B are important for HCV viral replication. Ledipasvir/sofosbuvir is available as a combination fixed-dose once-daily oral tablet.

Clinical Uses

Ledipasvir/sofosbuvir is currently licensed in the treatment of genotypes 1, 4, 5, and 6 chronic HCV without decompensated cirrhosis and genotypes 1 and 4 with decompensated cirrhosis. For treatment-naïve patients with or without cirrhosis, treatment should continue for 12 weeks. This regimen has been associated with a sustained virologic response of 99% at 12 weeks, and the duration of treatment can be safely reduced to as low as 8 weeks in selected patients with baseline HCV RNA levels <6 million IU/mL.

Toxicity

The most common side effects are headaches and fatigue. Significant drug interactions may occur with P-glycoprotein–inducing medications such as rifampin or St. John's wort. Ledipasvir/sofosbuvir should not be given to patients who are taking amiodarone because of the risk of bradycardia.

Resistance

Resistance to the individual component drug may occur but is rare. Ledipasvir is active against sofosbuvir-resistant viruses, and sofosbuvir retains activity against ledipasvir-resistant viruses, so the clinical significance of resistance mutations is not known.

SOFOSBUVIR/VELPATASVIR

Velpatasvir is a potent pangenotypic HCV NS5A inhibitor that is approved to treat hepatitis C patients in combination with sofosbuvir, an NS5B inhibitor. Sofosbuvir/velpatasvir is available as a combination in a fixed-dose, once-daily, oral tablet.

Clinical Uses

Sofosbuvir/velpatasvir is currently licensed in the treatment of adult patients with chronic hepatitis C genotype 1, 2, 3, 4, 5, or 6 infection with any degree of liver damage, including decompensated cirrhosis. The addition of ribavirin is recommended when treating patients with decompensated cirrhosis. The duration of treatment is 12 weeks, which is associated with sustained virologic response in more than 99% of patients in real-world situations.[A4]

Toxicity

The most common adverse reactions associated with 12 weeks of sofosbuvir/velpatasvir treatment are fatigue and headaches. Significant drug interactions may occur with P-glycoprotein–inducing medications (e.g., rifampin, St. John's wort) and cytochrome P-450–inducing medications (e.g., rifampin, phenytoin). Concomitant use of sofosbuvir/velpatasvir with amiodarone is contraindicated because of the risk of bradycardia.

Antiviral Resistance

Preexisting NS5A mutants do not seem to influence the outcome of sofosbuvir/velpatasvir treatment. NS5A-resistant variants that confer in vitro resistance to velpatasvir have been isolated from the blood of the few patients who relapse. The significance of these mutants is not completely understood.

SOFOSBUVIR/VELPATASVIR/VOXILAPREVIR

Velpatasvir is a potent pangenotypic HCV NS5A inhibitor to treat hepatitis C patients in combination with sofosbuvir, an NS5B inhibitor. Voxilaprevir is a second-generation HCV serine protease inhibitor. A single fixed-dose combination tablet of sofosbuvir, velpatasvir, and voxilaprevir is approved by the U.S. Food and Drug Administration (FDA) for treatment of HCV patients who have been previously treated with other direct-acting antivirals.

Clinical Uses

Sofosbuvir/velpatasvir/voxilaprevir is currently licensed in the treatment of adult patients who have chronic hepatitis C genotype 1, 2, 3, 4, 5, or 6 infection with any degree of liver damage without cirrhosis or compensated cirrhosis and who previously have been treated with an HCV direct-acting antiviral agent regimen. The duration of treatment is 12 weeks, which is associated with sustained virologic response in more than 99% of patients.[A5]

Toxicity

The most common adverse reactions associated with 12 weeks of sofosbuvir/velpatasvir/voxilaprevir treatment are fatigue, headaches, nausea, and diarrhea. Significant drug interactions may occur with P-glycoprotein–inducing medications (e.g., rifampin or St. John's wort) and cytochrome P-450–inducing medications (e.g., phenytoin, rifampin). Significant bradycardia can occur with concomitant use of sofosbuvir/velpatasvir/voxilaprevir and amiodarone, which is contraindicated.

Antiviral Resistance

Preexisting NS5A or NS3 mutants do not seem to influence the outcome of sofosbuvir/velpatasvir/voxilaprevir treatment. NS5A-resistant variants that confer in vitro resistance to velpatasvir have been isolated from the blood of few patients who relapse. The significance of these mutants is not completely understood.

GLECAPREVIR/PIBRENTASVIR

A fixed-dose combination tablet of glecaprevir, an NS3/4A protease inhibitor, and pibrentasvir, an NS5A inhibitor, is approved for the treatment of patients with chronic HCV genotype 1, 2, 3, 4, 5, or 6 infection without cirrhosis and with compensated cirrhosis (Child-Pugh A).

Clinical Uses

Glecaprevir/pibrentasvir is currently licensed in the treatment of adult patients with chronic hepatitis C genotype 1, 2, 3, 4, 5, or 6 infection with all degrees of liver damage without cirrhosis or compensated cirrhosis (Child-Pugh A). The duration of treatment, which is 8 weeks for those without cirrhosis and 12 weeks for those with cirrhosis, is associated with sustained virologic response in more than 99% of patients.[A6] The combination pill is also indicated for the treatment of adult patients who have HCV genotype 1 infection and who previously have been treated with a regimen containing an HCV NS5A inhibitor or an NS3/4A protease inhibitor but not for those who failed both. For treatment-experienced genotype 1 patients who have failed a previous NS5A inhibitor (but not NS3)-containing HCV regimen, 16 weeks of treatment is recommended. For treatment-experienced genotype 1 patients who have failed a previous NS3 inhibitor (but not NS5A) containing HCV regimen, 12 weeks of treatment is recommended. For HCV genotype 1, 2, 4, 5, or 6 patients who have failed previous HCV regimens that did not include either an NS3 or NS5A inhibitor, either 8 weeks (those without cirrhosis) or 12 weeks (with cirrhosis) is recommended. For HCV genotype 3 patients who have failed previous HCV regimens that did not include either an NS3 or NS5A inhibitor, 16 weeks is recommended. Glecaprevir/pibrentasvir is the preferred interferon-free regimen shown to be effective in patients with stage 4 or 5 chronic kidney disease and all genotypes of HCV.[A7]

Toxicity

The most common adverse reactions associated with 12 weeks of glecaprevir/pibrentasvir treatment are fatigue and headaches in about 10% of all patients. Carbamazepine, efavirenz, and St. John's wort may decrease concentrations of glecaprevir and pibrentasvir, so coadministration of these medications is not recommended.

Antiviral Resistance

Preexisting NS5A or NS3 mutants do not seem to influence the outcome of glecaprevir/pibrentasvir treatment. NS5A- and NS3-resistant variants that confer in vitro resistance to both drugs have been isolated from the blood of few patients who relapse. The significance of these mutants is not completely understood.

DACLATASVIR

Daclatasvir is an NS5A inhibitor that can be used in combination with either sofosbuvir or asunaprevir for treatment of hepatitis C infection.

Clinical Uses

Daclatasvir is approved by the FDA to treat adult patients with HCV genotype 1 or 3 infection in combination with sofosbuvir with or without ribavirin. The duration of treatment is 12 weeks. The treatment is approved for patients with or without cirrhosis, but the response rate is reduced in patients with genotype 3 and cirrhosis. Daclatasvir is metabolized through CYP3A, so the dose must be reduced with strong CYP3 inhibitors (e.g., ritonavir or itraconazole) and increased with CYP3A inducers (e.g., rifampin and phenytoin).

Toxicity

The most common adverse reactions associated with 12 weeks of sofosbuvir/daclatasvir treatment are headaches, fatigue, and nausea. The most common adverse reactions with concomitant use of ribavirin are headache, anemia, fatigue, and nausea. Because of the risk of significant bradycardia, concomitant use of sofosbuvir and amiodarone is contraindicated.

Antiviral Resistance

For patients with genotype 1 and cirrhosis, NS5A resistance reduces the efficacy of sofosbuvir/daclatasvir, so testing for resistance should be performed in this situation. For the other genotypes, preexisting NS5A mutants do not seem to influence the outcome of sofosbuvir/daclatasvir treatment. NS5A-resistant variants that confer in vitro resistance to daclatasvir have been isolated from the blood of few patients who relapse, but the significance of these mutants is not completely understood.

DACLATASVIR/ASUNAPREVIR

Asunaprevir is an HCV NS3 (serine protease) inhibitor, and daclatasvir is a potent HCV NS5A inhibitor. The combination is licensed to treat patients with hepatitis C in Europe and Japan.

Clinical Uses

The combination is approved for treatment of adults who have hepatitis C genotype 1 infection with compensated cirrhosis, who are ineligible or intolerant to interferon-based therapy, and who have failed to respond to interferon-based therapy. The combination has resulted in high response rates for both genotype 1a and 1b patients when treated for 24 weeks.[A8]

Toxicity

Nasopharyngitis, elevated aminotransferase levels, headaches, and fatigue are the most common adverse events.

Antiviral Resistance

Preexisting NS5A and NS3 polymorphisms can lead to reduced response rates with daclatasvir/asunaprevir combination, and hence these patients are treated for an extended period of time (24 weeks). In patients with genotype 1b, the addition of ribavirin results in high sustained virologic response with only 12 weeks of treatment.

GRAZOPREVIR/ELBASVIR

Grazoprevir is a second-generation HCV NS3/4A (serine protease) inhibitor, and elbasvir is a potent HCV NS5A inhibitor. The combination is available as a fixed-dose combination single tablet and is licensed to treat patients with hepatitis C genotypes 1 and 4.

Clinical Uses

The combination grazoprevir/elbasvir is indicated with or without ribavirin for treatment of chronic HCV genotypes 1 or 4 infection in adults. For genotype 1a patients, testing of NS5A-resistant–associated polymorphisms before treatment is indicated. For treatment-naïve adult patients with hepatitis C genotype 1a (without polymorphisms), genotype 1b, and genotype 4, a total duration of 12 weeks is recommended. For treatment-experienced patients with hepatitis genotype 1, addition of ribavirin and treatment for 12 weeks is recommended. For HCV patients with genotype 1a and with the NS5A polymorphisms, addition of ribavirin for a total duration of 16 weeks is recommended. A major advantage of this combination over sofosbuvir-based combination is use in patients with significant renal impairment, including patients in hemodialysis,[A9] because both drugs are metabolized by the liver. Conversely, this combination is contraindicated in patients with decompensated liver disease. Grazoprevir/elbasvir may be used in patients with stage 4 or 5 chronic kidney disease and HCV genotypes 1 or 4.

Toxicity

The most common adverse reactions associated with 12 weeks of grazoprevir/elbasvir treatment are headaches, fatigue, and nausea. Anemia is also associated with concomitant use of ribavirin. Since grazoprevir/elbasvir is metabolized by the liver, inducers (e.g., phenytoin, rifampin) and inhibitors (e.g., ritonavir, itraconazole) of the cytochrome oxidase CYP3A system will decrease or increase levels, respectively, and should be avoided.

Antiviral Resistance

Presence of five preexisting NS5A-resistant–associated polymorphisms (M28A/G/T, Q30H/K/R/Y, L31F/M/V, H58D, Y93H/N/S) in HCV genotype 1a is associated with lower response rates when treated with grazoprevir/elbasvir alone but results in high response rates when ribavirin is added and total treatment duration is extended to 16 weeks. Hence, resistant-associated polymorphism testing is recommended for patients with HCV genotype 1a.

SOFOSBUVIR

Clinical Uses

Sofosbuvir is currently licensed as a component of a combination antiviral treatment regimen with other direct-acting antiviral medications for all HCV genotypes. Sofosbuvir and ribavirin for 24 weeks without interferon is also effective for treating HCV genotype 1. In genotypes 2 and 3, sofosbuvir in combination with ribavirin for 12 or 24 weeks also has been associated with about a 90% rate of undetectable virus 3 weeks after therapy. For patients who cannot tolerate an interferon-based regimen (autoimmune disorders, decompensated hepatic disease, leukopenia, thrombocytopenia, anemia, or preexisting cardiac disease), sofosbuvir may be used with ribavirin for 24 weeks.

Toxicity

Common side effects include headache, fatigue, anemia, and diarrhea. Severe pancytopenias, insomnia, and depression also have been reported, especially when sofosbuvir is used in combination with pegylated interferon-alfa. Sofosbuvir is a substrate of drug transporter P-gp, and drugs that are potent P-gp inducers (e.g., rifampin or St. John's wort) may decrease sofosbuvir's plasma concentration. Significant bradycardia can occur when sofosbuvir is coadministered with amiodarone.

Resistance

The emergence of resistance while on sofosbuvir treatment is extremely rare.

BOCEPREVIR

Boceprevir is a protease inhibitor that binds to the NS3/4A of hepatitis C.

Clinical Uses

Boceprevir is currently licensed only for the treatment of genotype 1 in patients with compensated liver disease. It is used in combination with PEG-interferon and ribavirin in treatment-naïve patients as well as in patients who have not responded adequately to PEG-interferon and ribavirin. Boceprevir should not be used as monotherapy. Boceprevir is started 4 weeks after initiation of therapy with PEG-interferon and ribavirin, and combination therapy is continued for an additional 24 to 44 weeks based on virologic response. Subjects with undetectable HCV RNA level at weeks 8 and 24 may be considered for a shorter duration of treatment (28 weeks in total). In patients with evidence of virologic failure (HCV RNA level is >100 IU/mL at treatment week 12 or detectable at treatment week 24), treatment with all three drugs should be stopped. Because of its inferior efficacy, boceprevir is not considered a first-line therapy for hepatitis C.

Toxicity

Common side effects include fatigue, nausea, shivering, alopecia, and dysgeusia. Patients should be monitored for serious side effects such as anemia and neutropenia, which occasionally can be dose-limiting. Patients who develop anemia on combination therapy including boceprevir may be managed by reducing the ribavirin dose. Boceprevir is a strong inhibitor of cytochrome P450 3A4/5, so drug-drug interactions (including over-the-counter and oral contraceptives) must be considered.

Resistance

Resistance to boceprevir can occur on therapy. Because boceprevir and telaprevir are structurally similar, cross-resistant mutations may emerge, and patients should not be retreated with another protease inhibitor.

PEGYLATED INTERFERON-2B AND RIBAVIRIN

Clinical Uses

Neither ribavirin nor interferon should be used as monotherapy for hepatitis C. In genotype 1, the combination of PEG-interferon and ribavirin may be considered in treatment-naïve patients who cannot be given interferon-free regimens, although sustained virologic response rates are significantly inferior. Longer durations of treatment, up to 72 weeks, may improve virologic response. PEG-interferon and ribavirin should be administered for 24 weeks for HCV genotypes 2 and 3 and for 48 weeks for HCV genotypes 4, 5, and 6.

Toxicity

Common side effects of interferon administration include influenza-like symptoms (fever, chills, headache, malaise), but these symptoms usually become

less severe with repeated treatments. Major toxicities include bone marrow suppression, especially granulocytopenia and thrombocytopenia, which are generally reversible when therapy is discontinued. Neuropsychiatric disturbances may be manifested by depression, anxiety, somnolence, confusion, and behavioral changes. Other side effects include profound fatigue and anorexia, weight loss, hypothyroidism or hyperthyroidism, alopecia, and cardiotoxicity with arrhythmias and reversible cardiomyopathy. Some side effects (e.g., hypothyroidism) can present a year or longer after therapy has finished.

Systemic ribavirin is frequently associated with hemolytic anemia (in up to 60% in some series) and sometimes with electrolyte abnormalities, including hypocalcemia and hypomagnesemia. Arrhythmias, pruritus, rash, nausea, and myalgia have been reported, as have neurologic side effects, including insomnia and irritability. Ribavirin may be gonadotoxic and teratogenic in humans.

Special Considerations—HIV/HCV Coinfection

Initial treatment regimens for HCV/HIV-coinfected patients are the same as those recommended for individuals without HIV infection. However, when treating both HCV and HIV, drug-drug interactions and additive toxicities must be considered. Grazoprevir/elbasvir, glecaprevir/pibrentasvir, and sofosbuvir/velpatasvir/voxilaprevir should not be coadministered with HIV non-nucleoside reverse transcriptase inhibitors or protease inhibitors. Ledipasvir and velpatasvir can increase tenofovir levels, and HIV regimens without tenofovir or tenofovir alafenamide should be considered.

The HIV antivirals didanosine, stavudine, and zidovudine (Chapter 357) should not be used with ribavirin. Didanosine levels and its active metabolite are increased when administered with ribavirin and can cause hepatic failure, severe peripheral neuropathy, pancreatitis, and lactic acidosis. Zidovudine administered with ribavirin can cause severe neutropenic anemia, and the combination should not be used. If ribavirin is the preferred therapy, discontinuation of didanosine and zidovudine should be considered before initiation of ribavirin.

ANTIVIRALS FOR HERPESVIRUS INFECTIONS

ACYCLOVIR AND VALACYCLOVIR

Acyclovir, an acyclic analogue of the nucleoside guanosine, is converted to its active form through initial monophosphorylation by a virus-encoded thymidine kinase. Although normal human cells possess thymidine kinase, the affinity of acyclovir for viral thymidine kinase is approximately 200 times greater than for human thymidine kinase. The monophosphate then undergoes two additional host cell enzyme-mediated phosphorylations to acyclovir triphosphate (acycloguanosine triphosphate), which preferentially inhibits viral DNA polymerase. The higher concentrations of the activated form in infected cells and its affinity for viral polymerases result in low toxicity to normal host cells.

Valacyclovir is the L-valyl ester prodrug of acyclovir. Addition of the L-valyl ester allows greater oral absorption, after which valacyclovir is converted to acyclovir; the prodrug provides three to five times greater bioavailability than oral acyclovir.

Clinical Uses

Acyclovir and valacyclovir (Tables 328-4 to 328-6) are used principally to treat infections caused by herpes simplex virus (Chapter 345) and varicella-zoster virus (Chapter 346). Depending on the country, acyclovir is available in a topical ointment and cream, oral capsules, and intravenous and ophthalmic formulations. Valacyclovir is available only as an oral capsule.

Oral acyclovir or valacyclovir decreases the duration of symptoms by approximately 50% and reduces the duration of viral shedding by about 90% in initial episodes of genital herpes. Two or 3 days of therapy appear to be sufficient for recurrent genital herpes. Chronic suppression is highly effective in reducing clinical and viral recurrences, and valacyclovir reduces the risk for transmission of genital herpes simplex between heterosexual partners by 48%. For herpes labialis (cold sores), 1 day of therapy with oral valacyclovir improves time to healing and reduces pain, whereas acyclovir ointment has no consistent clinical benefit.

Parenteral acyclovir is indicated for the initial treatment of mucosal or cutaneous herpes simplex infection in immunocompromised patients, neonatal infections, and disseminated or organ-invasive infections in immunocompetent patients. A subsequent switch to oral valacyclovir is possible in some circumstances. High-dose parenteral acyclovir is the therapy of choice for treatment of herpes simplex encephalitis. Both acyclovir chemoprophylaxis and valacyclovir chemoprophylaxis reduce the incidence of recurrent herpes simplex in recipients of stem cell and solid organ transplants, but valacyclovir is superior for prevention of cytomegalovirus disease.

Acyclovir and valacyclovir are indicated for acute varicella infection (chickenpox) in adults. Parenteral acyclovir should be used for severe acute varicella infection, including pneumonia, encephalitis, thrombocytopenia, and severe hepatitis, or in immunocompromised hosts. Acyclovir is also indicated in varicella reactivation (zoster). In adults treated within 24 hours of the development of a varicella rash, acyclovir decreases the severity of disease and number of lesions, but oral valacyclovir may be more effective than oral acyclovir. Intravenous acyclovir is warranted for zoster in immunocompromised hosts.

Toxicity

Acyclovir and valacyclovir have excellent safety profiles and are generally well tolerated. Common side effects include nausea, vomiting, and headaches. Major adverse effects include renal dysfunction and central nervous system (CNS) toxicity. Dehydration and preexisting renal dysfunction predispose to the development of renal impairment. Neurologic side effects include tremor, myoclonus, confusion, lethargy, agitation, and hallucination. Renal dysfunction predisposes to the development of neurotoxicity. Neutropenia and other signs of bone marrow toxicity also have been reported rarely.

Antiviral Resistance

Despite widespread use of acyclovir, the development of resistance to herpes simplex virus in immunocompetent patients is uncommon (prevalence <1%). However, antiviral resistance is higher in immunocompromised patients, including those with HIV infection (prevalence of 5%) or bone marrow transplants (prevalence of up to 30%). Drug-resistant refractory varicella-zoster virus infections can occur in highly immunocompromised patients. Intravenous foscarnet or cidofovir may be effective for infections caused by acyclovir-resistant viruses.

PENCICLOVIR AND FAMCICLOVIR

Penciclovir is an acyclic guanine analogue that unlike acyclovir is not an obligate chain terminator and may be incorporated into DNA. Penciclovir is phosphorylated by viral thymidine kinase to penciclovir monophosphate, which is then converted to penciclovir triphosphate. Penciclovir demonstrates in vitro activity against varicella-zoster virus and herpes simplex virus comparable to that of acyclovir. The bioavailability of penciclovir after oral administration is less than 2%, so it is useful only as a topical treatment. In contrast, famciclovir is an oral prodrug that is deacetylated and oxidized in the liver to form penciclovir; the bioavailability of penciclovir averages 77% after administration of famciclovir.

Clinical Uses

Penciclovir and famciclovir are used to treat herpes simplex and varicella-zoster infections. Penciclovir is available as a topical cream and in some countries as an intravenous formulation. Famciclovir is available as a capsule.

Topical penciclovir, which is approved for the treatment of recurrent herpes simplex labialis, reduces pain and lesions by about 1 day. Famciclovir is approved for the treatment of recurrent herpes simplex labialis and genital infections and for herpes zoster, and its effectiveness is similar to valacyclovir or acyclovir. Famciclovir also may be used for suppressive therapy. Famciclovir and acyclovir provide similar times to resolution and rates of cure.

Toxicity

Topical penciclovir is well tolerated; the majority of adverse reactions are local irritation and mild erythema. Adverse effects of oral famciclovir include headache, dizziness, nausea, and diarrhea.

Antiviral Resistance

Penciclovir resistance in herpes simplex has been uncommon in immunocompetent patients but, like acyclovir resistance, more frequent in immunocompromised hosts (2.1%). Most acyclovir-resistant herpes simplex isolates are cross-resistant to penciclovir.

GANCICLOVIR AND VALGANCICLOVIR

Ganciclovir is an acyclic deoxyguanosine analogue with antiviral activity against multiple herpesviruses, including herpes simplex, varicella-zoster, cytomegalovirus (Chapter 347), Epstein-Barr virus (Chapter 348), and human herpesvirus 8. Ganciclovir has activity against herpes simplex and varicella-zoster, but it has more adverse reactions compared with acyclovir. It is much more active than acyclovir against cytomegalovirus and Epstein-Barr virus. The bioavailability of oral ganciclovir is less than 10%. Valganciclovir, the L-valyl prodrug of ganciclovir, increases the bioavailability of ganciclovir to approximately 60% after oral administration.

Clinical Uses

Ganciclovir is available as an oral capsule, a parenteral injection, and an ocular implant; valganciclovir is available only as a tablet. Ganciclovir and valganciclovir are effective for treatment of cytomegalovirus retinitis, for which they are

TABLE 328-4 ANTIVIRALS FOR HERPESVIRUS INFECTIONS

VIRAL INFECTION	DRUG	ROUTE	USUAL ADULT DOSAGE
HERPES SIMPLEX VIRUS			
Genital herpes			
First episode	Acyclovir	PO	400 mg tid or 200 mg five times/day for 7-10 days
	Famciclovir	PO	250 mg tid for 7-10 days
	Valacyclovir	PO	1 g bid for 7-10 days
Recurrent	Acyclovir	PO	800 mg tid for 2 days, or 400 mg tid or 200 mg five times/day for 5 days
	Famciclovir	PO	1000 mg bid for 2 doses (if HIV-infected: 500 mg bid for 7 days)
	Valacyclovir	PO	500 mg bid for 3 days or 1 g/day for 5 days
Suppression	Acyclovir	PO	400 mg bid
	Famciclovir	PO	250 mg bid
	Valacyclovir	PO	500 mg/day or 1 g/day (10 or more episodes/yr)
Orolabial herpes	Penciclovir 1%	Topical	Apply cream every 2 hr while awake for 4 days
	Acyclovir 5%	Topical	Apply cream five times/day for 4 days
	Docosanol 10%	Topical	Apply cream five times/day until healing
	Valacyclovir	PO	2 g q12h × 2 doses
	Acyclovir	PO	400 mg five times/day for 5 days
	Famciclovir	PO	1500 -mg single dose
Mucocutaneous disease	Acyclovir	IV	5 mg/kg/8 hr for 7-14 days
	Acyclovir	PO	400 mg five times/day for 7-14 days
	Valacyclovir	PO	500 mg or 1 g bid for 7-10 days
Encephalitis	Acyclovir	IV	10 mg/kg/8 hr for 10 days
Neonatal	Acyclovir	IV	10-20 mg/kg/8 hr for 14-21 days
Keratoconjunctivitis	Trifluridine	Topical	1 drop of 1% solution q2h up to 9 drops/day
	Vidarabine	Topical	½-inch ribbon of 3% ointment five times daily
Acyclovir-resistant herpes simplex	Foscarnet	IV	40 mg/kg q8-12 h for 2 to 3 weeks or until healed
CYTOMEGALOVIRUS			
Cytomegalovirus retinitis	Ganciclovir	IV	5 mg/kg/12 hr for 14-21 days (maintenance: 5 mg/kg/day)
	Valganciclovir	PO	900 mg bid for 21 days (maintenance: 900 mg/day)
	Cidofovir	IV	5 mg/kg once weekly × 2 weeks (maintenance: 5 mg/kg q2wk)
	Foscarnet	IV	60 mg/kg/8 hr or 90 mg/kg q12h for 14-21 days (maintenance: 90-120 mg/kg daily)
	Fomivirsen	Intravitreal	330 µg q2 weeks × 2 weeks (maintenance: 330 µg every month)
HIV infection, cytomegalovirus colitis or esophagitis	Ganciclovir	IV	5 mg/kg/12 hr for 14-28 days (until symptoms resolved)
Prophylaxis (transplantation)	Valganciclovir	PO	900 mg daily
	Ganciclovir	IV	5 mg/kg/12 hr for 7-14 days, then 5 mg/kg IV once a day
Prophylaxis (stem cell transplantation)	Letermovir	PO or IV	480 mg/day through 100 days post-transplant
Prophylaxis (advanced HIV infection)	Ganciclovir	IV	5 mg/kg daily
VARICELLA-ZOSTER VIRUS			
Varicella	Acyclovir	PO	800 mg qid for 5 days
Varicella in immunocompromised hosts	Acyclovir	IV	10 mg/kg/8 hr for 7-10 days
Zoster (shingles) in immunocompromised hosts	Acyclovir	IV	10 mg/kg/8 hr for 7-10 days
Zoster (shingles) in normal hosts	Acyclovir	PO	800 mg five times daily for 7-10 days
	Valacyclovir	PO	1 g tid for 7 days
	Famciclovir	PO	500 mg tid for 7 days

bid = twice daily; HIV = human immunodeficiency virus; IV = intravenously; PO = orally; tid = three times daily.

TABLE 328-5 MECHANISMS OF EXCRETION AND THRESHOLDS FOR DOSE ADJUSTMENT

	MAJOR ROUTE OF ELIMINATION	THRESHOLD FOR ADJUSTMENT IN RENAL INSUFFICIENCY OR FAILURE	ADJUSTMENT FOR HEPATIC FAILURE	ADJUSTMENT FOR OBESITY
Acyclovir IV	Renal	CrCl <50 mL/min	No adjustment	Dose by ideal body weight
Acyclovir PO	Renal	CrCl <25 mL/min/1.73 m^2	No adjustment	Dose by ideal body weight
Valacyclovir	Renal	CrCl <50 mL/min	No adjustment	Unknown
Famciclovir	Renal	CrCl <60 mL/min	No adjustment	Unknown
Foscarnet	Renal	CrCl <1.4 mL/min/kg	No adjustment	Unknown
Ganciclovir IV	Renal	CrCl <70 mL/min	No adjustment	Unknown
Valganciclovir	Renal	CrCl <60 mL/min	No adjustment	Unknown
Letermovir	Hepatic	Avoid IV if CrCl <50 mL/min	No adjustment in mild or moderate impairment	Unknown
Cidofovir	Renal	CrCl <55 mL/min	No adjustment	Unknown

CrCl = creatinine clearance.

TABLE 328-6 SIGNIFICANT ADVERSE EFFECTS (U.S. FDA BLACK BOX WARNING)

DRUG	BLACK BOX SYNOPSIS
Cidofovir	Renal impairment, including renal failure; prehydrate and use probenecid Neutropenia May be carcinogenic and teratogenic and may cause hypospermia or aspermia
Foscarnet	Nephrotoxicity; prehydrate Seizures related to minerals and electrolyte disturbances
Ganciclovir	Neutropenia, anemia, thrombocytopenia May be carcinogenic and teratogenic and may cause hypospermia or aspermia
Valganciclovir	Neutropenia, anemia, thrombocytopenia May be carcinogenic and teratogenic and may cause hypospermia or aspermia

comparably active. In the absence of immune reconstitution, long-term suppression therapy is necessary. They are also used for life-threatening cytomegalovirus diseases in patients with acquired immunodeficiency syndrome (AIDS) and other immunocompromised conditions and for prevention of cytomegalovirus disease in transplant patients. For immunocompromised patients with organ-invasive cytomegalovirus infections, intravenous ganciclovir provides clinical response rates of 70 to 90%, although response rates are lower for cytomegalovirus pneumonitis after stem cell transplantation or encephalitis in patients with AIDS. Oral valganciclovir provides long-term outcomes similar to those of intravenous ganciclovir for the treatment of cytomegalovirus disease.

Long-term prophylaxis with ganciclovir or valganciclovir reduces the incidence of cytomegalovirus disease after solid organ and stem cell transplantation, but this therapy has substantial side effects, including bone marrow suppression. These drugs also can be used as preemptive therapy for patients who have cytomegalovirus viremia or antigenemia. In the prevention of cytomegalovirus disease, preemptive valganciclovir therapy may be equally effective to chronic valacyclovir prophylaxis.

Toxicity

The most common adverse effect with ganciclovir and valganciclovir is bone marrow suppression, particularly neutropenia and thrombocytopenia, which occur in up to 50% of patients given intravenous ganciclovir. Fever, edema, phlebitis, headache, neuropathy, disorientation, nausea, anorexia, rash, and myalgias have also been reported with ganciclovir therapy. Intravitreal ganciclovir implants may cause vitreous hemorrhage and retinal detachment.

Antiviral Resistance

Ganciclovir resistance secondary to mutations in cytomegalovirus kinase and sometimes DNA polymerase is related to the length of ganciclovir exposure and the degree of immunosuppression. Resistance may be associated with progressive disease during continued ganciclovir use; foscarnet and cidofovir are alternative treatments.

LETERMOVIR

Letermovir is the first agent in the non-nucleoside 3,4-dihydro-quinazoline class of antivirals that inhibits the cytomegalovirus DNA terminase complex. This enzyme is required for viral DNA processing.

Clinical Uses

Letermovir use is indicated for a specific population—prophylaxis against active cytomegalovirus infection and disease in cytomegalovirus-seropositive recipients of an allogeneic hematopoietic stem cell transplant. Although ganciclovir and valganciclovir are effective in preventing cytomegalovirus infection, their use is limited by myelosuppression. Prophylaxis with letermovir prevents significantly more cytomegalovirus infections compared with placebo. The use of letermovir for treatment of active cytomegalovirus disease or in other indications has not been evaluated and therefore cannot be recommended until additional data are available.

Toxicity

The most common side effects are nausea, vomiting, and diarrhea, but they occur at similar rates as with placebo. The cardiac adverse event rate (primarily tachycardia and atrial fibrillation) is higher in patients receiving letermovir than placebo (13% vs. 6%). Letermovir is an inhibitor of cytochrome P450 3A (CYP3A) and organic anion-transporting polypeptide 1B1 and 1B3 transporters and has numerous drug-drug interactions, including with immunosuppressants and antimicrobial agents. Consultation with an experienced clinical pharmacologist is highly recommended. In patients with creatinine clearance less than 50 mL/min and receiving IV letermovir, accumulation of the intravenous vehicle, hydroxypropyl betadex, could occur.

Antiviral Resistance

The emergence of resistance while on letermovir is rare. Letermovir is fully active against cytomegaloviruses that are resistant to cidofovir, foscarnet, or ganciclovir.

FOSCARNET

Foscarnet is a pyrophosphate analogue that acts as a noncompetitive inhibitor of many viral RNA and DNA polymerases. When a nucleotide is incorporated into a DNA or RNA strand by a polymerase, pyrophosphate is released. Foscarnet directly inhibits viral polymerases without phosphorylation, so thymidine kinase-deficient, acyclovir-resistant herpes simplex and varicella-zoster viruses are susceptible to this agent.

Clinical Uses

For extraretinal cytomegalovirus disease, foscarnet has demonstrated efficacy similar to that of ganciclovir. Foscarnet is as effective as ganciclovir for the treatment of cytomegalovirus retinitis in patients with AIDS, and combination therapy with ganciclovir may be superior to monotherapy with either agent for recalcitrant retinitis. The choice of agent may be dictated by the side effect profile. Foscarnet is also effective for the treatment of acyclovir-resistant herpes simplex and varicella-zoster infections.

Toxicity

Nephrotoxicity with azotemia and proteinuria is dose limiting and occurs in more than one third of patients. A slow infusion rate and saline hydration reduce the risk. Other common side effects include anemia (30 to 50% of patients), granulocytopenia, diarrhea, nausea, vomiting, fever, seizures, paresthesia, headache, and genital ulcers. Marked electrolyte disturbances may develop, including hypophosphatemia, hypocalcemia, hypokalemia, and hypomagnesemia. Foscarnet can prolong the QT interval and be associated with cardiac arrhythmias, including ventricular tachycardia, ventricular fibrillation, and torsades de pointes.

Antiviral Resistance

The development of cytomegalovirus resistance to foscarnet as a result of mutations in viral DNA polymerase is uncommon except after prolonged administration. In AIDS patients with retinitis, foscarnet resistance is detectable in 13% of patients at 6 months and in 37% at 12 months.

CIDOFOVIR

Cidofovir, which is an acyclic phosphonate derivative of cytosine, is phosphorylated to its active diphosphate form by host cellular enzymes. Cidofovir diphosphate competitively inhibits viral DNA polymerase and viral DNA synthesis. Despite a short serum half-life, the antiviral effects are protracted because of prolonged intracellular concentrations of the phosphorylated metabolite.

Clinical Uses

Cidofovir is commercially available as an intravenous infusion, and investigational formulations have included topical gel and intravitreal and intralesional injections. Intravenous cidofovir is licensed for the treatment of cytomegalovirus retinitis. Because of its toxicities, it is generally reserved for when ganciclovir or foscarnet therapy is failing. Limited data suggest that intravenous cidofovir may be effective in other cytomegalovirus infections (pneumonitis, gastroenteritis), acyclovir- or foscarnet-resistant herpes simplex infections, certain forms of human papillomavirus disease, invasive adenoviral infections in transplant recipients, and possibly BK virus infection in renal transplant patients. In addition, in vivo and animal data suggest efficacy of cidofovir against smallpox, vaccinia, and monkeypox infections.

Toxicity

Dose-related nephrotoxicity, characterized by increased serum creatinine, proteinuria, and tubular dysfunction, is the main side effect of intravenous cidofovir. Adequate hydration and concomitant oral probenecid reduce the risk. Other common side effects include diarrhea, asthenia, nausea, vomiting, neutropenia, fever, and rash. Iritis, intraocular pressure changes, loss of visual acuity, and uveitis have been reported with intravenous cidofovir. Intravitreal cidofovir is effective but locally toxic.

Antiviral Resistance

Sustained exposure to cidofovir does not easily induce resistance, although resistance has infrequently been described in herpes simplex virus and cytomegalovirus.

FOMIVIRSEN

Fomivirsen, which is an antisense oligonucleotide that inhibits replication of cytomegalovirus, is currently available as an intravitreal injection that is effective for both newly diagnosed cytomegalovirus retinitis and cytomegalovirus retinitis failing usual therapies, although direct comparisons with other agents are lacking. Intravitreal administration of fomivirsen may cause increased intraocular pressure, iritis, vitreitis, and cataracts in 10 to 20% of patients. Topical corticosteroids may be useful for treating inflammatory changes.

DOCOSANOL

Docosanol, which is a 22-carbon saturated fatty alcohol that inhibits intracellular penetration of lipid-enveloped viruses, is approved as an over-the-counter cream for the treatment of herpes labialis. Frequent topical applications have shown reductions in time to cessation of pain and healing, but direct comparison to other agents is lacking. Local reaction, rash, and pruritus are common side effects.

ANTIVIRALS FOR INFLUENZA VIRUS INFECTIONS

Currently approved antivirals for the treatment of influenza include two neuraminidase inhibitors (oseltamivir and zanamivir), one endonuclease inhibitor (baloxavir marboxil), and two adamantanes (amantadine and rimantadine) (Tables 328-7 and 328-8). The choice of treatment for influenza should be dictated by circulating strains, antiviral resistance within those strains, and side effect profiles.[4]

OSELTAMIVIR, ZANAMIVIR, AND PERAMIVIR (NEURAMINIDASE INHIBITORS)

Oseltamivir, zanamivir, and peramivir are sialic acid analogues that inhibit influenza virus by competitively interacting with the neuraminidases of influenza A and B viruses. Influenza neuraminidase cleaves terminal sialic acid residues and destroys the receptors recognized by viral hemagglutinin. By this mechanism, the drugs inhibit the release of virus from infected cells, thereby preventing viral aggregates and spread within the respiratory tract.

Oseltamivir is administered orally as the phosphate prodrug, which is rapidly absorbed and hydrolyzed to the active form oseltamivir carboxylate. Bioavailability exceeds 75%. Conversely, the oral bioavailability of zanamivir is poor, so it is delivered as an orally inhaled powder. Peramivir is available only as a parenterally infused solution.

TABLE 328-7 ANTIVIRALS FOR INFLUENZA VIRUS INFECTIONS

VIRUS	DRUG	ROUTE	USUAL ADULT TREATMENT DOSAGE
Influenza A and B viruses	Oseltamivir	PO	75 mg bid for 5 days
	Peramivir	IV	600 -mg single IV dose
	Zanamivir	Inhalation	10 mg bid by inhaler for 5 days
	Baloxavir marboxil	PO	40 to ≤80 kg: 40-mg single dose >80 kg: 80-mg single dose
Influenza A virus	Amantadine	PO	100 mg bid or 200 mg daily for 5 days
	Rimantadine	PO	100 mg bid for 5 days

bid = twice daily; IV = intravenously; PO = orally.

Clinical Uses

Oseltamivir and zanamivir are effective for the treatment and prophylaxis of acute influenza A and B infections. Early treatment in adults decreases the duration and severity of illness and reduces lower respiratory tract complications, antibiotic use, and, with oseltamivir, hospitalizations. In low-risk ambulatory patients, oseltamivir alleviates symptoms faster than placebo, and it also decreases the risk for lower respiratory complications. In cohort studies of hospitalized patients, treatment with oseltamivir has been associated with a significant reduction in death. Zanamivir is also effective in alleviating symptoms and decreasing the risk for lower respiratory complications. Both zanamivir and oseltamivir are also highly effective for the prevention of influenza. Peramivir is licensed as a single-dose intravenous infusion for uncomplicated influenza. However, as a once- or twice-daily infusion in patients hospitalized with influenza, its efficacy is similar to oseltamivir. Combining oseltamivir with other antivirals (amantadine and ribavirin) does not improve efficacy over oseltamivir alone.[A10]

Toxicity

The most common side effects with oseltamivir are nausea and vomiting. They also may be associated with headache, rash, and possibly abnormal aminotransferase levels. Zanamivir is generally well tolerated, but severe bronchospasm has been reported primarily in patients with underlying airway disease. The most common side effects of peramivir are nausea, diarrhea, and mild neutropenia.

Antiviral Resistance

Oseltamivir resistance can be preexisting (widespread or local) or can emerge during therapy. In the immunocompromised host and possibly in individuals with H5N1 or H1N1 influenza, the development of resistance is associated with treatment failure. Zanamivir resistance is rare, and zanamivir retains clinical effectiveness against the most common oseltamivir-resistant variants.

BALOXAVIR MARBOXIL

Baloxavir marboxil is a prodrug that is converted by hydrolysis to baloxavir. Baloxavir, which is among a novel class of antivirals for influenza, inhibits the endonuclease activity of the polymerase acidic protein, which is an influenza-specific enzyme in the viral RNA polymerase complex and is responsible for viral gene replication.

Clinical Uses

Baloxavir marboxil is indicated for the treatment of acute influenza A and B infections in adults and children older than 12 years of age. Clinical efficacy is similar to oseltamivir, but baloxavir marboxil is unique in that it is administered as a single dose.[A11] When given as post-exposure prophylaxis, it can reduce household infections by about 60% and symptomatic infection by 85%.[A12]

Toxicity

Baloxavir marboxil is well tolerated with few side effects. The most common side effects are diarrhea and bronchitis and occurred in similar rates as placebo.

Antiviral Resistance

Circulating resistance to baloxavir is currently rare, although treatment-emergent resistance is 20 to 23% in patients 1 to 11 years of age and 3 to 11% patients 12 to 64 years of age.

AMANTADINE AND RIMANTADINE (ADAMANTANES)

Currently circulating H1N1 and H3N2 viruses are highly resistant to adamantanes. Unless circulating strains are documented as susceptible, these compounds should not be used. Amantadine and rimantadine are symmetrical tricyclic amines with activity against many influenza A viruses (Chapter 332).

TABLE 328-8 MECHANISMS OF EXCRETION AND THRESHOLDS FOR DOSE ADJUSTMENTS

	MAJOR ROUTE OF ELIMINATION	THRESHOLD FOR ADJUSTMENT IN RENAL INSUFFICIENCY OR FAILURE	ADJUSTMENT FOR HEPATIC FAILURE	SPECIAL ADJUSTMENT FOR THE ELDERLY
Amantadine	Renal	CrCl <50 mL/min/1.73 m^2	No adjustment	>65 years: 100 mg daily
Rimantadine	Hepatic and renal	CrCl <10 mL/min/1.73 m^2	100 mg daily	100 mg daily
Oseltamivir	Renal	CrCl <60 mL/min	No adjustment	
Peramivir	Renal	CrCl <50 mL/min	No adjustment	
Zanamivir	Renal	No adjustment	No adjustment	
Baloxavir marboxil	Hepatic	Not evaluated on CrCl <50 mL/min	No adjustment in mild or moderate impairment	Not evaluated in patients >65 years of age

CrCl = creatinine clearance.

By inhibiting the ion channel function of the M2 protein of influenza A, they interfere with uncoating of the virus and release of the viral genome.

Clinical Uses

Amantadine and rimantadine decrease the length and severity of uncomplicated influenza A virus infection by susceptible strains if they are initiated within the first 2 days after the onset of symptoms, but it is uncertain whether they reduce the risk for complications. Both drugs are formulated for oral administration, and amantadine also has a pediatric syrup formulation. In recent years, marked increases in antiviral resistance in community isolates have limited the utility of these drugs.

When adamantine-susceptible viruses are circulating, both rimantadine and amantadine are effective when they are used for prophylaxis (overall 66% average for rimantadine and 74% for amantadine). Despite prophylaxis, subclinical infections may still develop and elicit immune responses that are protective against antigenically related viruses.

Toxicity

Amantadine causes CNS side effects in 10 to 30% of healthy young adults who take the standard adult dose; the frequency is significantly lower with rimantadine. Neuropsychiatric side effects include anxiety, nervousness, insomnia, and, particularly in the elderly or those with renal insufficiency, hallucinations, confusion, disorientation, and psychosis or coma. Amantadine (or less often rimantadine) is associated with an increased risk for seizures. Both drugs cause gastrointestinal side effects. Orthostatic hypotension occurs in 1 to 5%. Anticholinergic side effects, including dry mouth, occur in amantadine recipients.

Antiviral Resistance

Single point mutations in M2 confer high-level resistance to these drugs and make them ineffective. Such resistant variants emerge commonly during treatment and are transmissible.

ANTIVIRALS FOR CORONAVIRUS INFECTIONS

REMDESIVIR

Remdesivir is an adenosine analog prodrug that inhibits viral RNA polymerases and has activity against several viruses, including Ebola virus (Chapter 351), Marburg virus (Chapter 351), Middle East respiratory system coronavirus (Chapter 334), and severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2; Chapter 337) and the disease it causes (coronavirus disease 2019 [COVID-19]).

Clinical Uses

When used in outpatients with COVID-19, remdesivir (200 mg intravenous loading dose followed by 100 mg on days 2 and 3) can reduce the risk of hospitalization or death by 87%[A13] and reduces the time to the alleviation of symptoms. When used in hospitalized patients with evidence of lower respiratory tract infection, a 5-day course appears to be as good as a 10-day course.[A14] Despite heterogeneity in the results of various randomized trials, meta-analysis of all studies suggests a net benefit for reducing time to recovery, progression to ventilation, and mortality.[A15,A16] Remdesivir is approved in the United States and in scores of other countries for patients who are hospitalized with COVID-19 and is recommended by the National Institute of Health COVID-19 Treatment Guidelines[5] but not by the World Health Organization[6] for hospitalized patients who require oxygen therapy.

Toxicity

Remdesivir can cause an increase in hepatic aminotransferase levels as well as gastrointestinal symptoms. Respiratory distress, hypotension, atrial fibrillation, and acute kidney injury have also been reported.

Antiviral Resistance

Although remdesivir resistance can occur in vitro, remdesivir resistance does not readily occur on treatment.

NIRMATRELVIR BOOSTED WITH RITONAVIR

Nirmatrelvir is an oral protease inhibitor that is active against M^{PRO}, a viral protease that plays a role in viral replication by cleaving the two viral polyproteins. Nirmatrelvir is administered with ritonavir, a cytochrome P450 (CYP) 3A4 inhibitor, to improve its pharmacokinetics. Alone, ritonavir has no activity against coronaviruses.

Clinical Uses

In nonhospitalized adults with mild to moderate COVID-19, ritonavir-boosted nirmatrelvir given within 5 days of the onset of symptoms reduces the risk of hospitalization or death through day 28 by 90% compared with placebo.[A17] Ritonavir-boosted nirmatrelvir (twice daily for 5 days) is recommended for treatment of non-hospitalized patients aged ≥12 years and weighing ≥40 kg at high risk for severe disease within 5 days of the onset symptoms. It is not recommended for patients who are taking potent cytochrome P450 (CYP) 3A4 inducers.

Toxicity

The most common adverse effects of ritonavir-boosted nirmatrelvir are dysgeusia, diarrhea, hypertension, and myalgia. The dose should be reduced in patients with moderate renal impairment, and this compound is not recommended in patients with an estimated glomerular filtration rate <30 mL/min. It also is not recommended for patients with severe hepatic impairment and should be used with caution in patients with pre-existing liver diseases, liver enzyme abnormalities, or hepatitis.

Antiviral Resistance

Missense mutation of the viral protease can occur in circulating strains, but currently no circulating mutations confer resistance to nirmatrelvir. In individuals with uncontrolled or undiagnosed HIV-1 infection, nirmatrelvir use may also lead to an increased risk of HIV-1 viral resistance to protease inhibitors.

MOLNUPIRAVIR

Molnupiravir is the oral prodrug of beta-D-N4-hydroxycytidine, which is a ribonucleoside with activity against several RNA viruses. Uptake of beta-D-N4-hydroxycytidine by viral RNA-dependent RNA polymerases results in viral mutations and lethal mutagenesis.

Clinical Uses

In non-hospitalized, unvaccinated adults, molnupiravir reduces the rate of hospitalization or death by 30% compared with placebo when started within 5 days after the onset of signs or symptoms of mild-to-moderate COVID-19.[A18] Although the different treatment options have not been directly compared in clinical trials, molnupiravir is generally recommended only when other therapies are not available or cannot be given, because molnupiravir has lower efficacy than the other options. Molnupiravir is not recommended in children or in pregnant or lactating woman.

Toxicity

The most common adverse effects of molnupiravir are diarrhea, nausea, and dizziness.

Antiviral Resistance

Although resistance can occur in vitro, molnupiravir resistance does not readily occur on treatment.

MONOCLONAL ANTIBODIES TO SARS-COV-2

Bamlanivimab/Etesevimab

Clinical Uses

Bamlanivimab (LY-CoV555) was the first monoclonal antibody that received U.S. FDA emergency use authorization. During development, treatment was subsequently modified to add a second monoclonal etesevimab (LY-CoV016). Bamlanivimab/etesevimab treatment of outpatients with symptomatic SARS-CoV-2 infection was associated a 3 to 4% decrease in COVID-19–related hospitalizations or emergency room visits.[A19]

The combination of bamlanivimab/etesevimab is indicated for treatment of mild-to-moderate non-hospitalized COVID-19 adult and pediatric patients at higher risk for progression to severe disease (generally defined as age ≥65 years of age, BMI >25, pregnancy, or an underlying medical condition associated with poor outcomes). It is given as 700 mg bamlanivimab and 1400 mg etesevimab administered together as soon as possible after positive viral test for SARS-CoV-2 and within 10 days of the onset of symptoms. Bamlanivimab/etesevimab should not be used in patients already hospitalized with COVID-19.

Antiviral Resistance

Some circulating variants, namely B.1.351 (Beta), P.1 (Gamma), and Omicron, have decreased susceptibility to bamlanivimab/etesevimab, and its use should be guided by the susceptibility of circulating strains.

Bebtelovimab

Clinical Uses

Bebtelovimab can improve symptoms and reduce viral load in patients with mild-to-moderate COVID-19. In high-risk patients, combining it with bamlanivimab/etesevimab does not provide additional benefit. Current guidance recommends it should be used only when ritonavir-boosted nirmatrelvir or remdesivir are not available, feasible to use, or clinically appropriate.

Antiviral Resistance

Bebtelovimab retains in vitro activity against Omicron BA.1 and BA.2 subvariants. Use with future variants should be guided by the susceptibility of circulating strains.

Casirivimab/Imdevimab

Clinical Uses

In outpatients with symptomatic SARS-CoV-2 infection, the monoclonal combination casirivimab/imdevimab can reduce hospitalization or all-cause death by half (6% in treated patients compared with 3% in controls).[A20] When given to exposed family members after one family member is diagnosed with SARS-CoV-2 infection, casirivimab/imdevimab is associated with 72% protection against symptomatic infections in the first week and 93% in subsequent weeks.

Casirivimab/imdevimab is indicated for the treatment of mild-to-moderate non-hospitalized COVID-19 adult and pediatric patients at higher risk for progression to severe disease. Casirivimab and imdevimab should be dosed at 600 mg of casirivimab and 600 mg of imdevimab administered together as a single intravenous infusion or by subcutaneous injection, as soon as possible after positive results of direct SARS-CoV-2 viral testing and within 10 days of the onset of symptoms. For prophylaxis in populations in high-risk environments, such as skilled nursing and assisted living facilities, the same dose is used. Casirivimab/imdevimab should not be used in patients already hospitalized with COVID-19.

Antiviral Resistance

Casirivimab/imdevimab should not be used for the Omicron variant given its decreased susceptibility to these antibodies. Use should be guided by the susceptibility of circulating strains.

Sotrovimab

Clinical Uses

Sotrovimab reduces the risk of COVID-19 progression to hospitalization or death by 85%.[A21] Sotrovimab (VIR-7831) is indicated for the treatment of mild-to-moderate non-hospitalized COVID-19 adult and pediatric patients at higher risk for progression to severe disease. Sotrovimab should not be used in patients already hospitalized with COVID-19.

Antiviral Resistance

This antibody maintained effectiveness against the Omicron BA.1 variant but does not have efficacy against Omicron BA.2 variant.[7] Use should be guided by the susceptibility of circulating strains.

OTHER ANTIVIRALS

RIBAVIRIN

Ribavirin is a purine nucleoside with antiviral activity against some DNA viruses and many RNA viruses, including influenza A and B, parainfluenza, coronaviruses including Middle East respiratory syndrome (Chapter 334), measles (Chapter 338), respiratory syncytial virus (Chapter 330), retroviruses (Chapter 360), arenaviruses such as Lassa virus (Chapter 351), and some hantaviruses (Chapter 351) and hepatitis C virus (Chapter 135).

Clinical Uses

Aerosol administration of ribavirin has been used to treat respiratory syncytial virus bronchiolitis and pneumonia in children and to treat influenza A and B infections. Limited benefit has been seen with oral ribavirin in uncomplicated influenza. Aerosol ribavirin combined with intravenous immune globulin, particularly with the anti-respiratory syncytial virus monoclonal antibody palivizumab, appears to reduce the mortality of respiratory syncytial virus infection in bone marrow transplant and other highly immunocompromised patients.

Systemic ribavirin reduces the mortality associated with Lassa fever and Asian (Korean) hemorrhagic fever with renal syndrome (Chapter 351), although not mortality in patients with hantavirus-associated cardiopulmonary syndrome. It appears to have activity in Congo-Crimean hemorrhagic fever and in Nipah virus infections. Ribavirin is often recommended as treatment of hemorrhagic fevers of unknown etiology or secondary to arenaviruses or bunyaviruses (Chapter 351).

Given the breadth of ribavirin's activity against many viruses, it is often used for emerging infectious diseases (e.g., severe acute respiratory syndrome [SARS] and Middle East respiratory syndrome). However, the concentrations needed to show efficacy in cell cultures and animal models may be significantly higher than can be obtained in humans. Caution is therefore urged when ribavirin is suggested for treating these diseases.

Ribavirin can improve the sustained virologic response for chronic hepatitis C infection when used with pegylated interferons, but the new directly acting antiviral agents are used without ribavirin. However, ribavirin is still used in patients with viral resistance to grazoprevir/elbasvir and in patients with cirrhosis (combined with sofosbuvir plus ledipasvir for treatment-experienced patients).

IMIQUIMOD

Imiquimod and the related compound resiquimod are topical immune response modifiers that lack direct antiviral effects. Instead, these agents induce activation of immune cells (monocytes, macrophages, natural killer cells) to produce antiviral cytokines, particularly interferon-α and tumor necrosis factor-α.

Topical imiquimod cream is approved for the treatment of condyloma acuminatum (Chapter 344). In immunocompetent patients, imiquimod leads to complete clearance of warts in 37 to 52% of patients. It is administered as a topical cream three times weekly for a maximum of 16 weeks and is washed off 6 to 10 hours after application.

Side effects are primarily local and include erythema, irritation, tenderness, and (less often) erosion. The side effects usually resolve with cessation of the drug.

329 THE COMMON COLD

BRUCE BARRETT

DEFINITION

The common cold is a clinical syndrome characterized by upper respiratory signs and symptoms (e.g., rhinorrhea, sneezing, nasal obstruction), which are frequently accompanied by sore throat, cough, and general malaise. The common cold is among the most prevalent of illness syndromes and is very costly in aggregate, especially considering the resulting absenteeism from school and work. Common cold is both a clinical and a cultural construction, and it results from a variety of etiologic agents.

The Pathogens

Human rhinoviruses are RNA viruses that infect the upper respiratory epithelium. Rhinoviruses are the most common viruses that cause upper respiratory symptoms in children and their family members.[1] The more than 150 rhinovirus genotypes are classified as species A, B, or C based on sequence homology. Rhinoviruses are important causes of exacerbations of chronic bronchitis (Chapter 76) and asthma (Chapter 75). Rhinovirus infection can cause bronchiolitis in infants and young children, and is the predominant cause of exacerbation of childhood asthma. Among elderly patients, especially those with lung disease, infection with rhinovirus and other cold viruses is an important cause of hospitalization, pneumonia, and death.[2,3]

The common cold illness syndrome also can be caused by parainfluenza viruses (Chapter 331), respiratory syncytial virus (Chapter 330), metapneumoviruses (Chapter 330), adenoviruses (Chapter 333), bocaviruses (Chapter 342), and influenza viruses (Chapter 332; Table 329-1).[4] Coronaviruses (Chapters 334 and 336), including severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) that is responsible for the coronavirus 19 (COVID-19) pandemic, also are common causes of the common cold. Bacterial pathogens such as *Mycoplasma pneumoniae* (Chapter 293), *Bordetella pertussis* (Chapter 389), group A streptococcus (Chapter 269) *Streptococcus pneumoniae* (Chapter 268), and *Haemophilus influenzae* (Chapter 277) are sometimes the only identifiable pathogen in a person who is experiencing the common cold syndrome, but the role of these organisms, which colonize the upper respiratory tract in healthy individuals, is not clear. Co-detection of more than one virus, or of a virus plus a bacterial pathogen, is fairly common.

EPIDEMIOLOGY

The incidence of common cold decreases with age, from an average of about six symptomatic episodes per year in young children to approximately two episodes per year in adults. Asymptomatic infections are also common. The incidence of illness is higher in adults who have occupational or household exposure to children and in young children who are cared for in child care centers. Common cold illnesses occur year-round in temperate climates but have a substantially increased incidence between the early autumn and late spring. Reasons for the seasonality of respiratory viruses[5] are poorly understood. In tropical climates, colds can occur year-round without defined seasonality.

TABLE 329-1 VIRUSES ASSOCIATED WITH THE COMMON COLD

VIRUS GROUP	ANTIGENIC TYPES	PERCENTAGE OF CASES
Rhinovirus	>150	30-60
Coronavirus	5	10-15
Parainfluenza virus	5	5
Respiratory syncytial virus	2	5-10
Influenza virus	3	5-15
Adenovirus	47	5
Metapneumovirus	2	5
Bocavirus	2	5-20

Based on data from: Byington CL, Ampofo K, Stockmann C, et al. Community surveillance of respiratory viruses among families in the Utah Better Identification of Germs-Longitudinal Viral Epidemiology (BIG-LoVE) study. *Clin Infect Dis*. 2015;61:1217-1224; Monto AS. Epidemiology of viral respiratory infections. *Am J Med*. 2002;112(Suppl 6A):4s-12s; and Szilagyi PG, Blumkin A, Treanor JJ, et al. Incidence and viral aetiologies of acute respiratory illnesses (ARIs) in the United States: a population-based study. *Epidemiol Infect*. 2016;144:2077-2086.

PATHOBIOLOGY

Respiratory pathogens are spread from person to person by direct contact with either infected individuals or contaminated objects in the environment, by large-particle aerosols, or by small-particle aerosols. Modes of transmission vary by agent and are influenced by a variety of factors, including distancing, mask-wearing, and handwashing. For example, respiratory syncytial virus (Chapter 330) may be spread by either direct contact or large-particle aerosols, and influenza (Chapter 332) may be spread more by small-particle aerosols. The SARS-CoV-2 virus appears to be spread more by respiratory droplets and aerosols than by direct contact.[6]

The common cold syndrome is initiated by viral infection of the epithelial cells in the nasal passageways or upper pharynx. Influenza and adenovirus produce obvious damage to the respiratory epithelium. Rhinovirus and respiratory syncytial virus, in contrast, have little or no detectable impact on the epithelium. Pathologic consequences of infection by SARS-CoV-2 are highly variable, from asymptomatic infection with minimal inflammation to highly invasive disease with a variety of pathologic manifestations and sequelae. Regardless of the histopathology, all of these viruses stimulate a nonspecific host inflammatory response that appears to be responsible for many of the symptoms associated with the common cold.

Nasal obstruction results from increased nasal blood flow and pooling of blood in the capacitance vessels of the nasal passageway. Sympathetic and parasympathetic pathways are involved. The increase in nasal secretion associated with the common cold may also contribute to nasal obstruction. Rhinorrhea is primarily a result of increased vascular permeability, with leakage of serum into the nasal secretions, which are composed of both transudates and exudates. Increased mucus production tends to contribute more to the secretions during the later stages of the illness.

Cough (Chapter 71) occurs in the majority of colds and tends to last longer than other symptoms. Cough during colds is produced by several different mechanisms, including infection-induced airway inflammation and irritation from mucus secretion or postnasal drip. Patients who smoke or who have asthma, reactive airway disease, or chronic obstructive pulmonary disease are at higher risk for cough.

The risk of infection after exposure to the respiratory viruses is primarily dependent on adaptive immune mechanisms, as indicated by the presence of specific neutralizing antibodies. Antibody responses to the rhinoviruses, adenoviruses, coronaviruses, and influenza viruses tend to be protective against subsequent infection. The frequency of infection with these viruses is a result of the large number of distinct serotypes of rhinovirus and adenovirus and the ability of the influenza viruses to behave as though there are multiple virus serotypes by virtue of the rapid mutation of surface antigens. The parainfluenza viruses, respiratory syncytial viruses, and metapneumoviruses produce very little protective immunity, so reinfection is common. As seen with SARS-CoV-2, relatively small genetic changes may result in variants that have different virulence, infectivity, and resistance to immune mechanisms.

Susceptibility to and pathogenesis of the common cold are multifactorial processes, with innate and adaptive immune mechanisms influenced by genetic predisposition, by previous antigen exposure, and by general health. Polymorphisms of mannose-binding lectin and various toll-like receptors may confer susceptibility or partial protection. Inflammatory cytokines associated with the severity of disease include various interferons, interleukins, and other factors, which rise markedly in nasal secretions but usually do not change much in the serum. Recent research suggests that the respiratory microbiome may be involved. Specific genes and epigenetic influences on the expression of those genes may predispose toward higher levels of inflammatory cytokines, and more severe respiratory illness.

Although specific mechanisms are not well understood, several decades of research have shown that susceptibility to common cold is influenced by mental health. Risk factors include perceived stress, social isolation, negative emotional style, and a history of stressful life events.

CLINICAL MANIFESTATIONS

The incubation of common cold illness is generally short, ranging from 2 to 8 days, although some adenoviruses may have an incubation of as long as 13 days. The common cold illness syndrome generally persists for 5 to 10 days, but a substantial proportion of individuals have colds that persist for longer or

ABSTRACT

Studies suggest that at least 3 of every 4 adults and 9 of 10 children will experience at least one cold in a given year, thereby making the common cold perhaps humanity's highest incidence illness. Average annual incidence deceases from five or six symptomatic episodes among very young children to one or two episodes per year among older adults. Viral infection of the upper respiratory tract stimulates immune and inflammatory mechanisms that lead to engorged blood vessels, vascular permeability, and mucus secretion, thereby producing rhinorrhea, sneezing, and nasal congestion; nociceptive stimulation that produces sore throat, headache, and myalgia; and mechanoreceptor stimulation, which involves the vagus nerve and produces cough. Generalized symptoms thought to be due to interferons and other inflammatory cytokines may lead to malaise, fatigue, headache, myalgia, or fever. Viral agents include rhinovirus, coronavirus, influenza, parainfluenza, respiratory syncytial virus, metapneumovirus, adenovirus, and bocavirus. The common cold is among the most costly of illnesses, due in large part to resulting absenteeism from school or work. Common cold symptoms may be partially alleviated with over-the-counter analgesics, decongestants, anticholinergics, and antitussives—but their effectiveness is limited, and side effects are common. For most viruses, effective antivirals do not yet exist, and antibacterial antibiotics are ineffective. Vaccinations for influenza and for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) help prevent infection, illness, hospitalization, and death, but they are not effective against other agents. Handwashing and general health maintenance may reduce infectivity and the overall burden of the common cold.

shorter periods of time. A sore or scratchy throat is frequently reported as the first symptom. Sneezing is also a common early symptom. Nasal obstruction and rhinorrhea develop rapidly and are often the most bothersome symptoms. Cough generally develops later in the illness, frequently is the most bothersome symptom during the latter phases of the common cold, and may persist for several weeks after all other symptoms have resolved. When asked to rate what bothers them most about their colds, people tend to identify general malaise or interference with daily activities as more important than the presence or severity of specific symptoms.

Physical findings are generally restricted to the upper respiratory tract. Swelling of the nasal epithelia and increased nasal secretion may be obvious to the examiner. A change in the color or consistency of nasal secretions is common during the course of the illness and is not indicative of sinusitis or bacterial superinfection. The posterior pharynx may show signs of inflammation similar to streptococcal pharyngitis. Paroxysmal cough or wheezing may occur.

DIAGNOSIS

The differential diagnosis of the common cold includes noninfectious disorders as well as other upper respiratory tract infections. Allergic rhinitis (Chapter 394) has a symptom complex similar to that of the common cold, although the presence of nasal or conjunctival itching suggests allergic disease. Most patients can reliably differentiate these illnesses.

Sinus involvement is usually present in uncomplicated cold illnesses. Superimposed bacterial sinusitis (Chapter 394) may be difficult to differentiate from an uncomplicated cold. Sino-nasal symptoms that persist without improvement for more than 10 days and that are accompanied by unilateral maxillary sinus pain and purulent discharge may suggest the presence of bacterial sinusitis, which actually is a relatively rare complication that may respond to antibiotics.

When symptoms are more severe—with rapid onset, feverishness, and headache or muscle aches, accompanied by sore throat or cough—an "influenza-like illness" may be diagnosed. Although influenza-like illness is more likely to be produced by influenza, parainfluenza, or SARS-CoV-2, any of the common cold viruses can produce this more severe variant of common cold.

In general, routine laboratory studies are not helpful for the diagnosis or management of the common cold. During epidemics such as COVID-19, or perhaps during the annual winter influenza epidemic, identification of the specific pathogen can be useful for epidemiologic purposes but will rarely influence treatment unless lower respiratory symptoms develop.[7] When signs and symptoms are more severe, a white blood cell count and inflammatory markers such as C-reactive protein may be useful for assessing the likelihood of pneumonia (Chapter 85). For patients who have pharyngeal exudates, swollen cervical lymph nodes, and feverishness, a rapid test for streptococcal pharyngitis (Chapter 269) may be useful. In epidemic conditions, advice from public health authorities should be taken into account.

TREATMENT

No treatments are scientifically proven to reduce the severity or duration of common cold illness significantly,[8] but many patients are inappropriately prescribed antibiotics.[9] Several treatments, however, may confer limited symptomatic benefit, which must be balanced against the potential for side effects.

Antivirals and Antibiotics

Specific antiviral therapy is generally not useful for the treatment of common cold. For proven influenza, the oseltamivir, zanamivir, peramivir, and baloxavir (Chapter 328) have a modest ameliorating effect, but the difficulty of distinguishing influenza from common cold and the need to start treatment very early in the illness are practical limitations to the use of these agents. Antibacterial therapy is of no benefit. Despite decades of efforts to reduce antibiotic prescribing for common cold, this practice remains disturbingly common.

Nasal Congestion

Both topical and oral adrenergic agents (Table 329-2) have limited efficacy as nasal decongestants.[A1] Although direct comparison has not been performed, it is generally accepted that topical over-the-counter agents, such as intranasal xylometazoline or oxymetazoline, are more effective than oral drugs for nasal congestion. Prolonged use of the topical adrenergic agents should be avoided to prevent the development of a rebound effect when the drug is discontinued (rhinitis medicamentosa). Systemic absorption of oxymetazoline and xylometazoline have rarely been associated with bradycardia, hypotension, and coma.

The systemic side effects of the oral adrenergic agents such as pseudoephedrine include central nervous system stimulation, which can cause insomnia, jitteriness, or palpitations. As a result, adrenergic decongestants should probably be avoided, especially by patients who have hypertension or heart disease. Nasal saline is an inexpensive and safe treatment for nasal congestion, but research to date has not demonstrated substantive benefit in common cold.

TABLE 329-2 PHARMACOLOGICAL TREATMENTS FOR THE COMMON COLD

DRUG	DOSE AND DURATION	SIDE EFFECTS
Topical adrenergic agent: oxymetazoline	2-3 sprays of 0.05% solution every 12 hr as needed for up to 3 days	Rebound nasal congestion with prolonged use Nasal stinging or burning
Oral adrenergic agent: pseudoephedrine	60 mg every 4-6 hr up to 240 mg/day as needed for nasal congestion	Insomnia Agitation
Antihistamine: chlorpheniramine	4 mg orally every 4-6 hr up to 24 mg/day as needed for rhinorrhea or sneezing	Sedation
Anticholinergic: ipratropium bromide	2 sprays per nostril of 0.06% solution every 6-8 hr as needed for rhinorrhea	Nasal dryness

Rhinorrhea

Rhinorrhea (nasal drainage, runny nose) is a hallmark symptom of the common cold. Adrenergic decongestants may provide limited relief but have significant side effects.[10] Blockade of cholinergic stimulation of glandular secretion using intranasal ipratropium bromide appears to reduce rhinorrhea in colds by about 25%. The most common side effect of intranasal ipratropium is a two-fold increase in nasal irritation and bleeding. First-generation (sedating) antihistamines, owing to their anticholinergic properties, may have mild beneficial effects on rhinorrhea[A2] but also can cause drying of the eyes, mouth, and nose.

Cough

Treatment directed at an underlying condition (e.g., asthma) might be helpful (Chapters 71 and 397). For example, if cough is caused by direct irritation owing to postnasal drip, it may respond to treatment with a first-generation antihistamine or ipratropium. If a more persistent cough is the result of virus-induced reactive airway disease, patients might possibly benefit from inhaled bronchodilator therapy (Chapter 75). The evidence for nonspecific cough suppression with codeine, dextromethorphan, guaifenesin, or moguisteine is quite limited, with insufficient data to support or refute clinical effectiveness. Herbal cough formulas including *Andrographis paniculata*, *Pelargonium sidoides*, or an ivy/primrose/thyme combination may have limited efficacy, but the evidence is limited and controversial. Because of a substantive placebo effect for cough, the choice of a safe antitussive agent may be guided by a patient's belief system and prior experience.

Pain-Related Symptoms

For sore throat, ear pain, headache, and body aches (myalgias), acetaminophen (e.g., 650 to 1000 mg every 4 to 6 hours) is the preferred initial treatment. Nonsteroidal anti-inflammatory agents (e.g., ibuprofen 200 to 400 mg every 4 to 6 hours or naproxen 275 to 550 mg every 6 to 8 hours) are equally effective for pain but can cause stomach upset and increase the risk of intestinal bleeding and kidney damage.

Combination Therapies

Combination cold therapies available without a prescription (containing, for example, analgesics, decongestants, antihistamines, and/or antitussives) may have modest benefits over placebo, but any symptomatic benefits should be weighed against potential side effects. Specific therapies targeted to an individual's symptoms of nasal obstruction, rhinorrhea, or sore throat are preferred, so as to avoid the cost and side effects of unnecessary medications.

Other Remedies

Zinc lozenges (e.g., zinc acetate or zinc gluconate, dosed at ≥75mg/day of elemental zinc) may improve common cold recovery rates by 20% or more.[A3] However, zinc lozenges are associated with bad taste, sore mouth, and occasional nausea; intranasal zinc may cause nasal irritation or nosebleeds. Neither vitamin C nor Echinacea formulations are of proven benefit for treating the common cold.[11]

PREVENTION

Chemoprophylaxis or immunoprophylaxis is generally not available for the common cold.[A4] Immunization or chemoprophylaxis against influenza (Chapter 332) and SARS-CoV-2 (Chapter 336) are useful to prevent colds caused by these pathogens.

Handwashing has undeniable benefits and can prevent spread of the common cold.[A5] Physical distancing and mask-wearing are now also established as effective ways to prevent acute respiratory infections, including the common cold. Vitamin C (ascorbic acid) has not been proven to prevent the common cold,[A6] though the regular ingestion of 400 to 1000 IU per day of vitamin D may reduce its incidence.[A7] Echinacea and the regular ingestion of probiotics have at most a modest benefit as preventive therapies.[A8] Both regular exercise and meditation may help to prevent or reduce the severity of the symptoms of common cold illness.[A9,A10]

PROGNOSIS

The common cold usually has little medical significance, and complete recovery can usually be expected. However, the common cold is costly, is highly prevalent, and can be temporarily debilitating. The common cold also can be complicated by otitis media (Chapter 394), sinusitis (Chapter 394), or pneumonia (Chapter 85), which may be a direct result of the viral infection or may be due to bacterial superinfection. Exacerbations of asthma (Chapter 75) and chronic bronchitis (Chapter 76) also are important complications of the common cold. For elderly who are frail or have advanced lung disease, the common cold can even lead to hospitalization or death. Rhinovirus infection within a family also appears to facilitate within-family transmission of *S. pneumoniae*, which may then result in pneumonia.

330 RESPIRATORY SYNCYTIAL VIRUS AND HUMAN METAPNEUMOVIRUS

H. KEIPP TALBOT AND EDWARD E. WALSH

RESPIRATORY SYNCYTIAL VIRUS

DEFINITION

Respiratory syncytial virus (RSV), which causes yearly winter outbreaks in temperate climates, is the most important cause of bronchiolitis and pneumonia in young infants, a common cause of illness in older children and young adults, and can be severe in elderly persons, adults with underlying cardiopulmonary disease, and adults who are severely immunocompromised.

The Pathogen

RSV is a single-stranded RNA-enveloped virus of the family Paramyxoviridae, genus *Pneumovirus*; it is related to human metapneumovirus. Two major transmembrane glycoproteins (G, attachment protein; F, fusion protein) carry neutralizing epitopes, and two nonstructural proteins (NS1 and NS2) block the antiviral activity of type I interferons, whereas a secreted form of G bearing a CX3C chemokine motif may modulate immune responses. Two major virus groups (A and B), each with multiple genotypes, are distinguishable.

EPIDEMIOLOGY

In the United States epidemics begin in the south in late fall, move steadily north, and peak in February and March in colder climates.[1] In tropical areas, RSV may occur throughout the year, with peaks during the rainy season. RSV annually causes approximately 100,000 hospitalizations and accounts for 60% of bronchiolitis and 25% of pneumonia cases in infants. Mortality is rare in the United States (<400 deaths annually), but deaths are substantially greater in developing countries. About half of infants become infected in their first winter and all by age 2. RSV is transmitted principally by direct contact with large-particle fomites of respiratory secretions rather than by small-particle aerosolization.

Between 1 and 3% of primary infections result in hospitalization, but lower socioeconomic status, crowding, underlying prematurity, congenital cardiac abnormalities, bronchopulmonary dysplasia, and immunosuppression are each associated with increased risk for serious disease. Severe disease is also associated with specific polymorphisms in the promoter regions of cytokine genes. Hospitalization is most frequent between the ages of 1 and 6 months, peaking at 2 months of age with a rate of 25.9 per 1000 children. However, the majority of hospitalized infants are normal healthy infants without identifiable risk factors. The overall burden of RSV in infants 0 to 6 months of age is 132 office visits, 55 emergency department visits, and 17 hospitalizations per 1000. Reinfection occurs frequently throughout life. Subsequent illness is less severe and hospitalization infrequent for persons ages 2 to 49 years, but severity increases with increasing age[2] and comorbid conditions such as diabetes, heart failure, chronic obstructive pulmonary disease, and end-stage renal disease.[3]

Though often not considered in adults, RSV infection is common and may be severe in the elderly. RSV accounts for 15 to 20% of medically attended outpatient respiratory illnesses in persons older than 45 years, and RSV-associated mortality among persons age 65 and older is about 90% as high as influenza A and greater than double that of influenza B. RSV infection is implicated in 6 to 15% of hospitalizations for acute pulmonary symptoms in the winter among community-dwelling elderly persons, numbers that are similar to those for influenza.[4]

RSV infection has been documented in up to 10% of bone marrow transplant recipients (Chapter 163), patients with acute leukemia (Chapter 168), and heart/lung transplant recipients (Chapters 46 and 87) during the winter months. In this setting, in-hospital outbreaks can develop quickly if patients are not adequately isolated.

PATHOBIOLOGY

The virus most commonly enters through the nose or eye and then spreads from the upper to the lower respiratory tract. Pathologic findings include a lymphocytic peribronchiolar infiltration with edema, obstruction, and necrosis. Bronchiolitis with multiple areas of atelectasis and pneumonia with interstitial infiltration of mononuclear cells, as well as alveoli filled by edema and necrosis, develop in infected patients.

CLINICAL MANIFESTATIONS

Infants experience upper respiratory symptoms of conjunctival injection, mucopurulent nasal discharge, cough, and low-grade fever after an incubation period of 2 to 8 days. Otitis media (Chapter 394) is often associated with secondary bacterial infection. After several days, lower respiratory tract symptoms appear in 25 to 50% of infants, with cough, wheezing, tachypnea, and use of accessory muscles as the disease progresses. Expiratory wheezes, rhonchi, and fine rales are the most common findings on lung examination. Sudden apnea may develop in the youngest infants. Hyperinflation and diffuse interstitial pneumonitis are the most frequent radiographic findings. High-titer virus shedding lasts 7 to 10 days, although immunocompromised infants may excrete virus for a month or longer, even when asymptomatic. Coinfection with other respiratory viruses occurs in up to 30% of patients, but it usually is neither clinically discernible nor definitively associated with more severe illness.

Adults with RSV typically begin with upper respiratory symptoms, but many patients have lower respiratory symptoms, including dyspnea and wheezing. Low-titer virus shedding often persists for 10 days or longer. In elderly

High-titer virus shedding lasts 7 to 10 days, although immunocompromised infants may excrete virus for a month or longer, even when asymptomatic. Coinfection with other respiratory viruses occurs in up to 30% of patients, but it usually is neither clinically discernible nor definitively associated with more severe illness.

Adults with RSV typically begin with upper respiratory symptoms, but many patients have lower respiratory symptoms, including dyspnea and wheezing. Low-titer virus shedding often persists for 10 days or longer. In elderly

ABSTRACT

Respiratory syncytial virus is a common respiratory pathogen affecting persons of all ages. The most severe illnesses occur in very young infants and frail elderly, as well as in patients with underlying cardiopulmonary disease or compromised immune systems. Clinical manifestations are dominated by upper and lower respiratory symptoms, with wheezing as a classic characteristic. Diagnosis is best made by testing respiratory secretions with molecular detection methods such as reverse transcription–polymerase chain reaction (RT-PCR). A vaccine is not currently available, and treatment options are limited. Prophylaxis with a monoclonal antibody is available for high-risk infants. Aerosolized ribavirin coupled with intravenous immunoglobulin may be efficacious in severely immunocompromised patients with lower respiratory tract disease.

Human metapneumovirus infection can range from asymptomatic carriage to fatal disease. The virus is the cause of nearly 10% of adult cases of hospitalized pneumonia. Diagnosis is by RT-PCR. Care is supportive. Most patients recover, but mortality can be high in immunocompromised patients.

human metapneumovirus

persons, RSV attack rates are 3 to 5% annually; wheezing is more common than with influenza (Chapter 332), whereas fever is less common. Symptoms can progress to respiratory failure,[5] especially in frail elderly persons, nursing home residents, or patients with underlying chronic obstructive pulmonary disease or heart failure.[6] Attack rates in nosocomial nursing home outbreaks average 10 to about 90%, with crackles and wheezes evident in a third of patients and radiographically confirmed pneumonia in approximately 10%. The incidence of bacterial superinfection in hospitalized adults with RSV is about 30%, similar to that of other common respiratory viruses, including influenza.

In bone marrow transplant recipients, RSV usually presents initially with upper respiratory symptoms. In about 30% of patients, lower respiratory tract disease follows, often with severe symptoms.

DIAGNOSIS

In infants, a presumptive diagnosis is suggested by typical symptoms during the epidemic season, but the diagnosis often is not considered and therefore delayed in adults.[7] Diagnosis can be made using sensitive molecular detection methods,[8] including reverse transcription–polymerase chain reaction (RT-PCR), transcription-mediated amplification (TMA), or loop-mediated isothermal application (LAMP).[9,10] Viral culture, which can take up to 10 days, has a sensitivity of only about 30%. Neither antigen detection by immunofluorescence nor enzyme immunoassay is useful in adults.

In immunocompromised patients, chest radiographs demonstrate diffuse interstitial and alveolar infiltrates. A useful clinical clue to the presence of RSV is the frequent presence of radiographically proven sinusitis. Upper respiratory tract symptoms distinguish this illness from cytomegalovirus pneumonia (Chapter 347).

TREATMENT

Therapy is generally limited to hydration and supplemental oxygen. Neither bronchodilators nor glucocorticosteroids have shown benefit in most studies. Inhaled ribavirin (2 g administered by aerosol three times daily for 5 or so days) may be beneficial for seriously ill infants and immunocompromised adults with RSV pneumonia, especially if begun before lower respiratory symptoms develop.[11] An experimental oral RSV-entry inhibitor and an oral nucleoside analog have shown promise in reducing the viral load in experimental human challenge models of RSV infection and are currently in clinical trials.[12]

Bacterial superinfection can develop, with *Streptococcus pneumoniae* (Chapter 268) and *Haemophilus influenzae* (Chapter 277) being the most frequent organisms. For such patients, appropriate antimicrobial treatment (Chapter 85) is mandatory.

PREVENTION

Adherence to standard infection control principles (e.g., gloves, gowns, frequent handwashing) substantially reduces nosocomial spread. Vaccines can reduce RSV-associated respiratory disease by about 70 to 80% and severe diseases by up to 90%, [A1–A3] and a vaccine is approved by the U.S. Food and Drug Administration for adults ages 60 years and older. Parenteral humanized RSV monoclonal antibody (palivizumab, 15 mg/kg monthly during the RSV season) has demonstrated benefit when administered prophylactically to specific high-risk infant groups,[13] but inhaled RSV antibodies have not been shown to improve clinical outcomes despite a somewhat more rapid decline in viral load.[A4]

PROGNOSIS

RSV infection in severely immunocompromised adults such as bone marrow transplant recipients (Chapter 163) and those with acute leukemia (Chapter 168) undergoing cytotoxic chemotherapy can carry a 60% mortality rate when pneumonia develops. Lymphopenia (<100/μL) and high-dose total body irradiation are associated with more severe disease, but progression to pneumonia is very unusual in patients with an absolute lymphocyte count above 1000/μL. In lung transplant recipients, bronchiolitis obliterans syndrome may occur in 10 to 50% of patients as a late sequela of RSV infection.

Mortality is rare in otherwise healthy infants but can reach 37% in infants with cardiac disorders. In children, a link between severe bronchiolitis and subsequent asthma remains unresolved. In normal infants and healthy adults, the outcome is generally good, but the risk of mortality in adults is higher with RSV than with influenza.[14,15] Hospitalized older adults can have mortality rates of about 10%.

HUMAN METAPNEUMOVIRUS

Human metapneumovirus, which is a negative-sense single-strand RNA virus in the *Pneumoviridae* family, was first identified in 2001 in children with bronchiolitis. It is recognized primarily as a cause of upper and lower respiratory tract illness in infants and young children, with a peak age of hospitalization at 6 to 12 months.

EPIDEMIOLOGY

The virus generally circulates in late winter to early spring in the Northern Hemisphere, at the same time that the incidence of RSV is usually declining. Similar to RSV, human metapneumovirus is transmitted primarily by direct contact with respiratory secretions. Some data suggest that nearly every child will be infected, but immunity is incomplete. Reinfection is common throughout life and is generally mild, although older adults, immunocompromised individuals, and patients with chronic cardiopulmonary disease are at greatest risk of severe disease.[16] In one study, symptomatic human metapneumovirus developed in 1 to 6% of adults annually. During the same period, human metapneumovirus was identified in 8.5% of adults who were hospitalized with pneumonia and 13% of adult pneumonias that required intensive care. Chronic heart and lung disease were present in more than 50% of hospitalized patients.

PATHOBIOLOGY

Human metapneumovirus is difficult to isolate in cell culture. In response to infection, innate immunity via interferons is key to preventing viral replication. In symptomatic individuals, however, human metapneumovirus induces a poor innate immune response, because it interferes with pattern recognition and cell signaling pathways triggered by interferon-associated genes.[17]

CLINICAL MANIFESTATIONS

Infection can range from asymptomatic carriage to fatal disease. Symptoms are similar to RSV and influenza,[18,19] and wheezing is a prominent finding in hospitalized persons. Radiographic abnormalities are present in two thirds of hospitalized cases, with centrilobular nodules, ground-glass opacities, and consolidation most common.[20] In hospitalized adults, bacterial coinfection can be identified in about 25 to 40% of cases.

Human metapneumovirus can be particularly severe in immunocompromised children and adults, especially in hematopoietic cell transplant recipients (Chapter 163). Approximately 50% of stem cell recipients who have upper respiratory symptoms will develop lower tract disease, and prior exposure to antibiotics is associated with higher risk.

DIAGNOSIS

Diagnosis relies on RT-PCR, but discordance between RT-PCR results from upper and lower respiratory samples can make diagnosis difficult.[21]

PROGNOSIS

Most patients recover completely without sequelae. However, 30-day mortality is about 7% among patients who require hospitalization and can be about 40% in hospitalized stem cell transplant recipients.

TREATMENT AND PREVENTION

Care is primarily supportive, and no therapies are currently proven to be effective, even in immunocompromised patients. No vaccines are in clinical trials.

331 PARAINFLUENZA VIRAL DISEASE

GEOFFREY A. WEINBERG AND KATHRYN M. EDWARDS

EPIDEMIOLOGY

The human parainfluenza viruses are ubiquitous, with a worldwide geographic distribution.[1,2] Their transmission is principally by large-particle fomites via close person-to-person contact. Parainfluenza virus activity displays both endemic and epidemic patterns, with each serotype preferring different age groups and triggering distinct clinical syndromes but with enough overlap to preclude specific diagnosis based solely on clinical and epidemiologic grounds. In the United States, about 55% of confirmed cases are type 3, about 18% are type 1, about 14% are type 2, and about 13% are type 4.[3]

Primary infection with human parainfluenza virus occurs early in childhood. Of the parainfluenza viruses, type 3 generally infects infants first, such that 50 to 67% of infants demonstrate serologic evidence of infection by 1 year of age. Parainfluenza virus types 1 and 2 most commonly infect children between 2 and 5 years of age. Parainfluenza virus type 4 less commonly causes symptomatic respiratory infections, but it may frequently be found as a viral coinfection with other pathogens.

Until the early 1960s, type 1 human parainfluenza virus caused endemic annual disease in the United States. For the past several decades, however, type 1 human parainfluenza virus has been associated with biennial outbreaks in the fall of odd-numbered years. Infections with type 2 human parainfluenza virus largely follow this same curious pattern but occur much less commonly than type 1 human parainfluenza virus infections. Infections with type 3 human parainfluenza virus have remained endemic throughout the year, with peaks in the late spring. Biennial outbreaks of type 1 human parainfluenza virus also occur in even-numbered years in Australia. During the 2020-2021 severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic, the typical seasonal circulation patterns of human parainfluenza virus changed, but whether new seasonal patterns will emerge is not yet certain.[4,5] The incubation period for all serotypes of human parainfluenza virus is between 3 and 6 days in experimentally infected adults, but natural infections in children have incubation periods of 2 to 4 days.

The human parainfluenza viruses are second only to respiratory syncytial virus as the cause of acute upper and lower respiratory tract infections in young children in the United States. In a population-based study of children younger than 5 years hospitalized with fever or acute respiratory tract infection, 7% of children had laboratory-confirmed human parainfluenza virus infection (by cell culture and molecular amplification techniques), compared with 19% with respiratory syncytial virus and 6% with influenza A or B virus infections. The hospitalization rate for human parainfluenza virus infection in children younger than 5 years was 1.02 per 1000 children per year. Extrapolating to the entire U.S. population, these data suggest that approximately 23,000 human parainfluenza virus hospitalizations occur annually in children younger than 5 years. The rates of emergency department and outpatient health care visits attributable to human parainfluenza virus infections in young children are 10- to 50-fold greater than hospitalization rates. Further, immunity to human parainfluenza virus infection is neither complete nor durable, so older children and adults can exhibit symptomatic infection, sometimes leading to office visits and hospitalization.

PATHOBIOLOGY

The human parainfluenza virus genome encodes six structural proteins. The hemagglutinin-neuraminidase (HN) and fusion (F) proteins, which are exposed on the bilayered lipid envelope surrounding the helical nucleocapsid–RNA complex, mediate both attachment to host sialic acid–containing glycoproteins and penetration of the virus into susceptible mammalian cells. These proteins have retained their antigenic stability for many years, unlike the "drift and shift" of the hemagglutinin and neuraminidase of influenza viruses. The four serotypes of human parainfluenza virus are called types 1 to 4, including two subgroups (A and B) of type 4 virus.

The human parainfluenza viruses replicate in the ciliated epithelial cells that line the respiratory tract on its luminal surface.[6] This selective tropism is consistent with the absence of invasive disease or viremia in the immunocompetent host, although rare cases of human parainfluenza virus 3 aseptic meningitis have been described. Syncytium formation, which is noted in viral cell cultures and in the lungs of immunocompromised patients with severe pneumonia, is not thought to be important in typical infections of previously healthy individuals.

CLINICAL MANIFESTATIONS

Primary Infection

Illness associated with primary human parainfluenza virus infection varies by age and viral serotype. Underlying medical conditions such as cardiopulmonary compromise and immune disorders increase the severity of disease. Large cohort and longitudinal family studies have shown that human parainfluenza virus infections are responsible for about 65% of croup, 20 to 40% of lower respiratory infection, and 20% of upper respiratory infection in young children. The majority of children have experienced primary human parainfluenza virus infection by the time they enter elementary school. Thus, although human parainfluenza virus also causes upper respiratory infections in adults, these are reinfections rather than primary infections (see later). In general, type 1 and type 2 infections are most commonly associated with croup, whereas type 3 infection often presents as undifferentiated febrile illness, bronchiolitis, or pneumonia.

Infection typically begins with upper respiratory signs and symptoms, notably coryza, rhinorrhea, pharyngitis without cervical adenopathy, and low-grade fever. Symptoms typically persist for 3 to 5 days. About 15 to 25% of infected children develop signs of croup or progress to lower respiratory tract disease (e.g., bronchiolitis, pneumonia) indistinguishable from respiratory syncytial virus infection. Some data suggest that human parainfluenza virus may occasionally involve the myocardium and central nervous system.[7]

Croup is characterized by a raspy barking cough with notable inspiratory stridor, dyspnea, and respiratory distress. These symptoms, which are generally spasmodic, result from subglottic inflammation and edema. On occasion, severe stridor may develop and make differentiation from epiglottitis caused by *Haemophilus influenzae* type b (Chapter 277) difficult, although epiglottitis is much less common in the United States since universal Hib vaccination became routine in 1990.

Croup is very rare in adults but has been associated with human parainfluenza virus in isolated case reports. Epiglottitis is seen more often in adults, but it is more commonly associated with staphylococcal or streptococcal infection. Epiglottitis is a medical emergency for patients of all ages and must be distinguished from croup to allow proper therapy, including emergent intubation of the airway. For patients who are judged to have a stable enough airway to permit urgent radiography rather than emergent tracheostomy, the differences between these two entities are clearly shown in lateral neck radiographs, on which subglottic edema and narrowing are seen with croup, and swelling of the epiglottis is seen with epiglottitis (Figs. 331-1 and 331-2). Children with bronchiolitis or pneumonia caused by human parainfluenza virus have cough, rales, and wheezing associated with hypoxia, and their chest radiographs often exhibit air trapping.

Reinfection

Reinfection with human parainfluenza virus is less severe and typically causes rhinorrhea in normal children and adults. Reinfection with human parainfluenza virus is estimated to account for 1 to 15% of all acute respiratory illnesses in adults, with the majority of infections presenting as simple upper respiratory tract infections. However, as with respiratory syncytial virus, some adults may develop more severe disease that requires hospitalization and even ventilatory support.[8] In such patients, fever, cough, dyspnea, and wheezing are common. Radiographic changes, primarily lobar or interstitial infiltrates, are seen in more than 50% of adults hospitalized with human parainfluenza virus infection.

Elderly and Immunocompromised Patients

Parainfluenza virus infections often cause severe pneumonia in immunocompromised individuals. Nursing home outbreaks of human parainfluenza virus infection with a high incidence of pneumonia have been reported. Among healthy elderly residents of long-term care facilities, human parainfluenza virus infections are as common as infections caused by influenza A virus, influenza B virus, or respiratory syncytial virus. Ten percent of children and 2 to 7% of adults with leukemia or hematopoietic stem cell or solid organ transplant recipients develop human parainfluenza virus infections, with about 90% of those due to type 3 human parainfluenza virus.[9] Although 80 to 90% of human parainfluenza virus infections in patients with malignancy are community acquired, nosocomial outbreaks have occurred in stem cell transplant units.

ABSTRACT

Human parainfluenza viruses are important causes of a wide spectrum of respiratory illnesses, including the common cold, otitis media, croup, bronchiolitis, and pneumonia. Four viral serotypes exist, called type 1 through type 4 human parainfluenza virus. In young children, infection often occurs in the first year of life; later, all four types of human parainfluenza virus may cause initial and repeated respiratory infections, most commonly in children in years 2 to 5 but also throughout adulthood. Infection of young children with type 3 human parainfluenza virus tends to present as undifferentiated febrile illness, bronchiolitis, or pneumonia. Infections with type 1 and type 2 human parainfluenza viruses tend to present as croup—an illness characterized by a croupy, barking cough; inspiratory stridor; and respiratory distress. Reinfections are generally less severe and typically present as a common cold with rhinorrhea. However, infections with human parainfluenza virus may be severe among immunocompromised hosts, such as patients with a malignancy or after organ or stem cell transplantation. Diagnosis of human parainfluenza virus infection is best made by reverse transcription–polymerase chain reaction of respiratory tract secretions. Therapy of childhood croup is with oral dexamethasone, given as a one-time dose to reduce the need for hospitalization and intubation. Specific antiviral medications and preventive vaccines for human parainfluenza virus infection are under investigation. Less specific, supportive measures such as aerosolized ribavirin and intravenous immunoglobulin infusion may be considered for severe human parainfluenza virus infection in immunocompromised patients.

Approximately 25% of human parainfluenza virus–infected stem cell transplant recipients develop lower respiratory disease, mostly in the first 100 days after transplantation, when lymphopenia and neutropenia are most pronounced. The strongest identified risk factors for human parainfluenza virus infection in these individuals are neutropenia, lymphopenia, more severe disease, and the use of corticosteroids, especially at higher doses.[10] Fever, cough, dyspnea, and sputum production are the most common symptoms. Coinfections with *Aspergillus* (Chapter 311) and other pathogens have been reported in hematopoietic stem cell transplant recipients with pneumonia as well.

DIAGNOSIS

Although human parainfluenza virus may be suspected on clinical and epidemiologic grounds, specific diagnosis requires isolation of the virus or detection of viral antigen or RNA in respiratory secretions. Reverse transcription–polymerase chain reaction (RT-PCR) assays are highly sensitive and specific for diagnosis. Alternatively, cultures of monkey kidney or human embryonic kidney cells can be used to grow the virus, with cytopathic effects detected in 5 to 10 days (except for type 4 human parainfluenza virus, which requires up to 3 weeks). Rapid direct or indirect immunofluorescence tests are less sensitive and specific than culture or PCR but still are used in some clinical laboratories.

Definitive diagnosis of parainfluenza infection in adults, even by RT-PCR, may be more difficult than in children, presumably because less virus is shed in partially immune adults. However, virus can usually be recovered from the nasopharyngeal secretions or bronchoalveolar lavage fluid in hematopoietic stem cell transplant recipients with pneumonia.

TREATMENT

Specific antiviral treatment of human parainfluenza virus infection is currently unavailable. Aerosolized ribavirin has in vitro activity against human parainfluenza virus and is approved for use in respiratory syncytial virus infection. Although it has shown few benefits in immunocompromised children and adults with severe human parainfluenza virus pneumonia, even when administered with concomitant intravenous immunoglobulin, some experts will offer aerosolized or intravenous ribavirin, with or without intravenous immunoglobulin, to immunocompromised patients with severe disease.[11]

For previously healthy children with croup, general comfort, which usually means sitting in the lap of a parent or caregiver, is widely recommended. Humidified air (mist) repeatedly has been shown to have no benefits and actually is associated with adverse effects, including anxiety, difficulty with cardiorespiratory monitoring, and bacterial and fungal contamination of both hot and cold mist humidifiers. Oxygen may be given by holding the end of the tubing near the nose and mouth ("blow-by" oxygen).

Children with mild to moderate croup (i.e., without stridor or significant chest wall indrawing at rest or with stridor and indrawing but without agitation) may

be given oral dexamethasone, 0.6 mg/kg body weight, and observed; if they improve, they may be discharged to home.[A1] Children with severe croup (stridor, chest wall indrawing, and agitation) may benefit from blow-by oxygen, inhaled racemic epinephrine (0.05 mL/kg body weight of a 2.25% solution of racemic epinephrine for nebulization, up to a maximum dose of 0.5 mL) or nebulized L-epinephrine (0.5 mL/kg of 1: 1000 L-epinephrine, up to a maximum dose of 5 mL) and concomitant dexamethasone. Children should be admitted to the hospital if no significant clinical improvement is seen after several hours of observation and therapy.

Oral dexamethasone is as effective as intramuscular dexamethasone or nebulized budesonide and easier to administer. Corticosteroids decrease the need for hospitalization and return visits, decrease length of stay both in emergency departments and after hospital admission, and decrease the need for intubation. In general, there are no reasons to institute either antibiotic therapy or short-acting bronchodilator therapy in children with croup.

Investigational therapies for human parainfluenza virus infection include both nonspecific and specific measures. Inhalation of heliox (helium-oxygen mixture) may decrease the work of breathing and improve gas exchange in children with moderate to severe croup, but adequately controlled clinical trial data are not yet available.[A2] The novel antiviral agent DAS181, a sialidase fusion protein with activity against both influenza and parainfluenza viruses, has shown beneficial effects in a small number of adults and children with severe human parainfluenza virus infection and is undergoing further clinical trials.[12]

PREVENTION

Clinical trials of live attenuated human parainfluenza virus vaccines are ongoing.[13] Two approaches have been taken to produce live-attenuated intranasal vaccines to type 3 human parainfluenza virus. One approach has been to attenuate a viral isolate by repeated cold-temperature passage and manipulation by recombinant technology. A second has been to use a related but nonvirulent bovine parainfluenza virus as a backbone in which to insert type 3 human parainfluenza virus genes to produce an attenuated chimeric vaccine virus. Another vaccine candidate under study uses the chimeric bovine-human type 3 parainfluenza virus but with an additional respiratory syncytial virus gene inserted into the vaccine virus genome in an attempt to prevent both of these common infections in young children. Vaccines against type 1 human parainfluenza virus infection (with or without respiratory syncytial virus components) also are under development.

PROGNOSIS

In otherwise healthy children, mortality after human parainfluenza virus infection is less than 0.1%. By comparison, mortality after human parainfluenza virus pneumonia in patients undergoing stem cell transplantation is as high as 10 to 30%.

332 INFLUENZA

MICHAEL G. ISON AND NELSON LEE

DEFINITION

Influenza is an acute febrile respiratory viral illness that usually occurs in annual outbreaks of varying severity and occasionally causes worldwide epidemics (pandemics). Increasingly, sporadic zoonotic infections, sometimes associated with limited human-to-human transmission, are being reported.

Influenza viruses infect the respiratory tract, are highly contagious, and classically produce prominent systemic symptoms early in the illness. Influenza infection causes various clinical syndromes in adults, including nonfebrile common colds (Chapter 329), pharyngitis (Chapters 269 and 397), tracheobronchitis (Chapter 84), pneumonia (Chapter 85), and a range of nonrespiratory complications. Conversely, infections with other respiratory viruses, such as respiratory syncytial virus (RSV [Chapter 330]) or adenovirus (Chapter 333), may produce influenza-like illness. Influenza A viruses have caused five pandemics of varying severity within the past 120 years (E-Table 332-1). The 1918–1919 pandemic caused at least 500,000 deaths in the United States and more than 40 million worldwide,[1] whereas the 2009 H1N1 pandemic was associated with substantially less mortality. Seasonal epidemics can cause enormous morbidity, economic loss, and often substantial mortality. Each year in the United States, seasonal influenza epidemics are associated with an estimated 4.3 to 16.7 million medical visits, 140,000 to 710,000 hospitalizations, and 12,000 to 56,000 respiratory and circulatory deaths. During the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic (Chapter 336), masking and social isolation led to a decline in diagnosed cases of influenza.[2]

The Pathogen

Influenza viruses belong to the family Orthomyxoviridae and are divided into four types (A, B, C, and D) based on their protein composition and other properties (E-Table 332-2). The virion (E-Fig. 332-1) is a medium-sized enveloped pleomorphic particle covered with two types of surface glycoprotein spikes: the trimeric hemagglutinin (H or HA) and the tetrameric mushroom-shaped neuraminidase (N or NA). The envelope is composed of a lipid bilayer overlying the matrix (M1) protein that surrounds the viral genome, which consists of eight segments of single-stranded negative-sense RNA in influenza A and B viruses. Influenza C viruses have seven segments and only a single surface glycoprotein. Genomic replication occurs in the nucleus of infected cells, and multiple cellular proteins and pathways are involved during the infection of host cells.

Whereas influenza B and C viruses are principally human pathogens, influenza A viruses primarily infect aquatic birds and sometimes establish lineages that circulate in other animal hosts, including other avians, swine, horses, marine mammals, and dogs. Influenza D appears to be pathogenic in cattle and perhaps other domestic animals. Influenza A viruses are further classified into subtypes on the basis of their HA and NA glycoproteins. Sixteen HA and nine NA subtypes are currently recognized in avians, and two others are recognized in bats. Only three HAs (H1, H2, and H3) and two NAs (N1 and N2) have been documented thus far in epidemic and pandemic human influenza A viruses, although other HAs (e.g., H5, H6, H7, H9, H10) and NAs (e.g., N4, N7, N8, N9) have been found in zoonotic infections. Each strain is identified by type, subtype if influenza A, location of isolate, sample number, and year of isolation (e.g., A/California/04/2009 (H1N1)).

EPIDEMIOLOGY

Antigenic and Genetic Variation

Influenza viruses are unique among the respiratory viruses with regard to their extent of genetic and antigenic variation, epidemic behavior, and frequent association with excess mortality during community outbreaks—characteristics and pathogenicity that exemplify human influenza virus's efficient host-to-host transmissibility. The changing antigenicity of the surface glycoproteins largely accounts for repeated influenza epidemics. Antibody to HA can neutralize viral infectivity and is thus the major determinant of immunity. Current vaccines are based largely on inducing hemagglutination-inhibition (HAI) or neutralizing antibodies to HA. Anti-NA antibody limits viral replication and probably reduces the severity of infection. Variation involves either relatively minor (antigenic drift) or major (antigenic shift) changes in antigenicity. Significant antigenic variation is much less frequent with influenza B or C than with influenza A.

Antigenic drift results from point mutations in the HA gene segment that cause amino acid substitutions in at least one of five key antigenic sites on HA. Drift can also occur in NA and in T-cell epitopes on internal proteins. Antigenic variants emerge frequently (every year or every few years) within an influenza A or B virus. For example, the original H3N2 variant, A/Aichi/68, has undergone successive drifts resulting in epidemic strains that include the recent circulation of A/Kansas/14/2017 (H3N2)-like virus. Immunologic selection favors transmission of the new variant over the old because of the less frequent presence of antibody to the new virus in the population.

be given oral dexamethasone, 0.6 mg/kg body weight, and observed; if they improve, they may be discharged to home.[A1] Children with severe croup (stridor, chest wall indrawing, and agitation) may benefit from blow-by oxygen, inhaled racemic epinephrine (0.05 mL/kg body weight of a 2.25% solution of racemic epinephrine for nebulization, up to a maximum dose of 0.5 mL) or nebulized L-epinephrine (0.5 mL/kg of 1: 1000 L-epinephrine, up to a maximum dose of 5 mL) and concomitant dexamethasone. Children should be admitted to the hospital if no significant clinical improvement is seen after several hours of observation and therapy.

Oral dexamethasone is as effective as intramuscular dexamethasone or nebulized budesonide and easier to administer. Corticosteroids decrease the need for hospitalization and return visits, decrease length of stay both in emergency departments and after hospital admission, and decrease the need for intubation. In general, there are no reasons to institute either antibiotic therapy or short-acting bronchodilator therapy in children with croup.

Investigational therapies for human parainfluenza virus infection include both nonspecific and specific measures. Inhalation of heliox (helium-oxygen mixture) may decrease the work of breathing and improve gas exchange in children with moderate to severe croup, but adequately controlled clinical trial data are not yet available.[A2] The novel antiviral agent DAS181, a sialidase fusion protein with activity against both influenza and parainfluenza viruses, has shown beneficial effects in a small number of adults and children with severe human parainfluenza virus infection and is undergoing further clinical trials.[12]

PREVENTION

Clinical trials of live attenuated human parainfluenza virus vaccines are ongoing.[13] Two approaches have been taken to produce live-attenuated intranasal vaccines to type 3 human parainfluenza virus. One approach has been to attenuate a viral isolate by repeated cold-temperature passage and manipulation by recombinant technology. A second has been to use a related but nonvirulent bovine parainfluenza virus as a backbone in which to insert type 3 human parainfluenza virus genes to produce an attenuated chimeric vaccine virus. Another vaccine candidate under study uses the chimeric bovine-human type 3 parainfluenza virus but with an additional respiratory syncytial virus gene inserted into the vaccine virus genome in an attempt to prevent both of these common infections in young children. Vaccines against type 1 human parainfluenza virus infection (with or without respiratory syncytial virus components) also are under development.

PROGNOSIS

In otherwise healthy children, mortality after human parainfluenza virus infection is less than 0.1%. By comparison, mortality after human parainfluenza virus pneumonia in patients undergoing stem cell transplantation is as high as 10 to 30%.

332 INFLUENZA

MICHAEL G. ISON AND NELSON LEE

DEFINITION

Influenza is an acute febrile respiratory viral illness that usually occurs in annual outbreaks of varying severity and occasionally causes worldwide epidemics (pandemics). Increasingly, sporadic zoonotic infections, sometimes associated with limited human-to-human transmission, are being reported.

Influenza viruses infect the respiratory tract, are highly contagious, and classically produce prominent systemic symptoms early in the illness. Influenza infection causes various clinical syndromes in adults, including nonfebrile common colds (Chapter 329), pharyngitis (Chapters 269 and 397), tracheobronchitis (Chapter 84), pneumonia (Chapter 85), and a range of nonrespiratory complications. Conversely, infections with other respiratory viruses, such as respiratory syncytial virus (RSV [Chapter 330]) or adenovirus (Chapter 333), may produce influenza-like illness. Influenza A viruses have caused five pandemics of varying severity within the past 120 years (E-Table 332-1). The 1918–1919 pandemic caused at least 500,000 deaths in the United States and more than 40 million worldwide,[1] whereas the 2009 H1N1 pandemic was associated with substantially less mortality. Seasonal epidemics can cause enormous morbidity, economic loss, and often substantial mortality. Each year in the United States, seasonal influenza epidemics are associated with an estimated 4.3 to 16.7 million medical visits, 140,000 to 710,000 hospitalizations, and 12,000 to 56,000 respiratory and circulatory deaths. During the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic (Chapter 336), masking and social isolation led to a decline in diagnosed cases of influenza.[2]

The Pathogen

Influenza viruses belong to the family Orthomyxoviridae and are divided into four types (A, B, C, and D) based on their protein composition and other properties (E-Table 332-2). The virion (E-Fig. 332-1) is a medium-sized enveloped pleomorphic particle covered with two types of surface glycoprotein spikes: the trimeric hemagglutinin (H or HA) and the tetrameric mushroom-shaped neuraminidase (N or NA). The envelope is composed of a lipid bilayer overlying the matrix (M1) protein that surrounds the viral genome, which consists of eight segments of single-stranded negative-sense RNA in influenza A and B viruses. Influenza C viruses have seven segments and only a single surface glycoprotein. Genomic replication occurs in the nucleus of infected cells, and multiple cellular proteins and pathways are involved during the infection of host cells.

Whereas influenza B and C viruses are principally human pathogens, influenza A viruses primarily infect aquatic birds and sometimes establish lineages that circulate in other animal hosts, including other avians, swine, horses, marine mammals, and dogs. Influenza D appears to be pathogenic in cattle and perhaps other domestic animals. Influenza A viruses are further classified into subtypes on the basis of their HA and NA glycoproteins. Sixteen HA and nine NA subtypes are currently recognized in avians, and two others are recognized in bats. Only three HAs (H1, H2, and H3) and two NAs (N1 and N2) have been documented thus far in epidemic and pandemic human influenza A viruses, although other HAs (e.g., H5, H6, H7, H9, H10) and NAs (e.g., N4, N7, N8, N9) have been found in zoonotic infections. Each strain is identified by type, subtype if influenza A, location of isolate, sample number, and year of isolation (e.g., A/California/04/2009 (H1N1)).

EPIDEMIOLOGY

Antigenic and Genetic Variation

Influenza viruses are unique among the respiratory viruses with regard to their extent of genetic and antigenic variation, epidemic behavior, and frequent association with excess mortality during community outbreaks—characteristics and pathogenicity that exemplify human influenza virus's efficient host-to-host transmissibility. The changing antigenicity of the surface glycoproteins largely accounts for repeated influenza epidemics. Antibody to HA can neutralize viral infectivity and is thus the major determinant of immunity. Current vaccines are based largely on inducing hemagglutination-inhibition (HAI) or neutralizing antibodies to HA. Anti-NA antibody limits viral replication and probably reduces the severity of infection. Variation involves either relatively minor (antigenic drift) or major (antigenic shift) changes in antigenicity. Significant antigenic variation is much less frequent with influenza B or C than with influenza A.

Antigenic drift results from point mutations in the HA gene segment that cause amino acid substitutions in at least one of five key antigenic sites on HA. Drift can also occur in NA and in T-cell epitopes on internal proteins. Antigenic variants emerge frequently (every year or every few years) within an influenza A or B virus. For example, the original H3N2 variant, A/Aichi/68, has undergone successive drifts resulting in epidemic strains that include the recent circulation of A/Kansas/14/2017 (H3N2)-like virus. Immunologic selection favors transmission of the new variant over the old because of the less frequent presence of antibody to the new virus in the population.

ABSTRACT

Influenza is an acute febrile respiratory viral illness that usually occurs in annual outbreaks of varying severity and that occasionally causes worldwide epidemics (pandemics). Increasingly, sporadic zoonotic infections, sometimes associated with limited human-to-human transmission, are being documented. Among influenza A viruses, antigenic drift and antigenic shift contribute to the annual risk of epidemics and global pandemics. Prevention is best achieved through annual vaccination. Current treatment is focused on the early use of neuraminidase inhibitors or baloxavir marboxil to reduce complications and speed recovery.

E-TABLE 332-1 ANTIGENIC SUBTYPES OF INFLUENZA A VIRUS ASSOCIATED WITH PANDEMIC AND PANDEMIC-LIKE INFLUENZA

YEAR ONSET	INTERVAL (YR)	SUBTYPE DESIGNATION	EXTENT OF ANTIGENIC CHANGE IN INDICATED SURFACE PROTEIN†	SEVERITY OF PANDEMIC (MORTALITY)*
1889	42-59	H3N?	H+++N?	Severe
1918	29	H1N1‡	H+++N+++	Very severe
1957	39	H2N2	H+++N+++	Severe
1968	11	H3N2	H+++N–	Moderate§
1977	9	H1N1	H+++N+++	Negligible‖
2009	32	H1N1	H++N++	Mild-moderate‖

*Severity is defined as the global impact on mortality.
†Compared with antecedent or cocirculating virus.
‡Formerly designated H0N1 (swine virus prototype) or Hsw1N1.
§The population had some immunity to N2 neuraminidase.
‖The older population was largely immune because of previous infection with earlier circulating, antigenically identical (1977) or related (2009) viruses; those born after 1957 were primarily affected. The impact of the 2009 pandemic virus, based on estimated years of life lost, was comparable to that observed in the 1968 pandemic in the United States.
+ = Minor change; ++ = moderate change; +++ = major change; – = no change.

E-TABLE 332-2 INFLUENZA A VIRUS PROTEINS

DESIGNATION	LOCATION (APPROXIMATE SIZE)	FUNCTION	OTHER
Hemagglutinin (HA)	Surface, transmembrane (566 aa)	Cell attachment via sialic acid–bearing receptors and penetration; fusion of host cell and viral membranes	Type-, subtype-, and strain-specific antigens; key antigen in inactivated vaccines
Neuraminidase (NA)	Surface, transmembrane (454 aa)	Virus release and spread; enzymatic activity causes removal of sialic acid residues from receptors	Type-, subtype-, and strain-specific antigens; activity linked to risk for pneumonia; site of action of neuraminidase inhibitors
M1 or matrix	Internal (252 aa)	Major structural envelope protein; virus assembly	Type-specific antigen; conserved T-cell epitopes
M2	Surface, transmembrane (97 aa)	Ion channel; virus uncoating and budding	Influenza A only; site of action of amantadine/rimantadine; ectodomain as possible vaccine candidate
Nucleoprotein (NP)	Internal (498 aa)	Major ribonucleoprotein complex component; associated with RNA and polymerase proteins	Type-specific antigen; conserved T-cell epitopes
Polymerase proteins (PB1, PB2, PA)	Internal (PB1-757 aa, PB2-759 aa, PA-716 aa)	Viral RNA replication and mRNA transcription (RNA-dependent RNA polymerase, cap-binding, endonuclease)	Determinant of replication efficiency; specific PB2 mutations associated with mammalian adaptation; site of action of polymerase inhibitors
NS1	Nonstructural (230 aa)	Multifunctional; regulation of viral RNA and protein synthesis; host protein interactions	Interferon antagonist; inhibition of innate immune signaling
NEP (NS2)	Internal (121 aa)	Nuclear export factor	From splicing of NS1 mRNA
PB1-F2	Nonstructural (87 aa)	Pro-apoptotic factor; pro-inflammatory effects; interferon antagonist	Expressed from 1+ reading frame of PB1 of certain viruses
PA-X	Nonstructural (41-61 aa)	Endonuclease activity; inhibition of host protein synthesis	Modulation of the host response to infection; expressed by 1+ ribosomal frame-shifting

NOTE: Influenza B also has eight gene segments, one of which encodes both NA and NB proteins, the latter a membrane protein of uncertain function, and another encoding the M1 (matrix) and BM2 proteins, the latter functioning as an ion channel but not inhibited by adamantanes. Nonstructural proteins are present only in infected cells. Other small nonstructural proteins (PB1-N40) have been described in influenza A and are under study.
mRNA = messenger RNA.

E-FIGURE 332-1. Diagram of influenza virus structure. Eight segments of viral RNA are contained within the lipid envelope and matrix (M1) shell. Each segment codes for one or more proteins that form the virus or regulate its intracellular replication. The presumed functions of each are listed in E-Table 332-2. HA = hemagglutinin; NA = neuraminidase; NEP = nuclear export protein; NP = nuclear protein; PA, PB1, PB2 = polymerase proteins. (Courtesy Dr. Robert G. Webster.)

Antigenic shift results from the appearance of a novel influenza A virus with HA, NA, or both HA and NA glycoproteins that are new to humans or that reappear after decades of absence. Because of the lack of population immunity, a new strain that is efficiently transmitted from person to person can cause pandemic disease. The origins of new pandemic strains and the basis for their subsequent seasonal circulation remain incompletely understood. Avian influenza viruses have most frequently served as the reservoir of new genes for pandemic viruses. Reassortment of gene segments may occur when two influenza viruses simultaneously infect a single cell and in reassortment events in which human viruses acquired avian genes led to both the 1957 and 1968 pandemic viruses. Because swine can support replication of both human and avian viruses, they have been postulated to serve as a mixing vessel for the generation of new strains or as the host in which avian viruses can adapt to mammals. The 2009 H1N1 pandemic virus arose as a quadruple reassortant that derived gene segments from Asian and North American swine lineage viruses that harbored genes derived from swine, avian, and human viruses.

Multiple reassortment events may occur over a period of years before a pandemic virus emerges. For example, the 1918 pandemic virus appears to have been composed primarily of avian genes that underwent adaptation in a mammalian host before causing the pandemic. Frequent intra-subtypic reassortment also occurs among seasonal human influenza A viruses and sometimes leads to new antigenic variants and sometimes to altered virulence.

Epidemic or Interpandemic Influenza

An epidemic is an outbreak of influenza confined to one geographic location. In temperate climates, community epidemics of influenza A virus infection often have a characteristic pattern, typically reaching a sharp peak in 2 or 3 weeks after initial recognition and persisting for 6 to 10 weeks. Increased numbers of schoolchildren with febrile respiratory illness are often the first indication of influenza in a community, soon followed by illnesses in adults and, 1 to 2 weeks later, by increased hospital admission of patients with influenza-related complications. Hospitalization rates in high-risk persons increase two- to five-fold during major epidemics. School and employment absenteeism increases, as does mortality from pneumonia and underlying conditions, especially in older adults during A/H3N2 epidemics. Epidemics occur almost exclusively during the late autumn and winter months in temperate areas, but activity may extend into spring months. Because of the seasonal differences between northern and southern hemispheres, seasons cycle between the hemispheres. Influenza activity may occur year-round in the tropics or display other patterns. The reasons for the distinct seasonality of influenza in temperate climates are uncertain but may include the school calendar, increased close indoor contact, and low absolute humidity, which affects airborne transmissibility. Winter holidays delay the peaks of seasonal epidemics and shift the risk of infection toward adults. Outbreaks sometimes occur in tour groups (land or ship) and in chronic care facilities during summer months, particularly after the appearance of a drift variant. Regional differences in the timing, magnitude, and causative viruses of influenza outbreaks are common. During epidemics, overall attack rates typically range from 5 to 20% in adults. Attack rates of 40 to 50% may occur in semiclosed populations, such as on hospital floors and chronic care facilities, as well as in highly susceptible age groups such as children. Influenza A and B viruses, two different influenza A subtypes, two different influenza B lineages, or two different strains within a single subtype may co-circulate or occur sequentially during one season in a given location. In addition, simultaneous outbreaks of influenza A virus and RSV or other respiratory viruses occur. Strains circulating at the end of one season's epidemic are sometimes responsible for the next season's outbreak (the so-called herald wave phenomenon).

Pneumonia- and influenza-related deaths fluctuate annually, with peaks in the winter months in temperate climates. When such deaths exceed the expected threshold, the cause is typically influenza A, but influenza B virus or RSV can occasionally be responsible. Influenza A/H3N2-dominant seasons are associated with two to three times higher mortality rates than are nonpandemic H1N1- and B-dominant seasons. Although mortality is usually greatest during pandemics, substantial mortality occurs with epidemics. During seasonal influenza, more than 85% of pneumonia- and influenza-related deaths occur in persons aged 65 years and older. Mortality risk is especially high in those aged 85 years and older. Cardiovascular events (e.g., myocardial infarction) and worsening of other chronic diseases (e.g., asthma, chronic obstructive pulmonary disease) contribute substantially to the increased mortality during influenza epidemics.

Pandemic Influenza

Pandemics of influenza A result from the emergence of a new virus capable of sustained person-to-person transmission and to which the population contains no or limited immunity. The virus spreads worldwide, often circulating outside of the usual influenza season, and usually infects persons of all ages. Preexisting immunity due to prior infection with antigenically related viruses can provide partial protection, as occurred in older adults during the 2009 H1N1 pandemic. Pandemics are associated with high morbidity rates, especially in children, and sometimes notably increased mortality rates in pregnant women and young and middle-aged adults. For example, more than 90% of deaths in the 1918 and 2009 pandemics occurred in persons younger than 65 years. In the 2009 pandemic, adults hospitalized with H1N1 were more likely to have severe pneumonia, shock, sepsis, and organ failure and to require intensive care unit (ICU) care than were patients with seasonal influenza.

The interval between pandemics is variable (10 to 40 years) and unpredictable. The most severe pandemics have been associated with major antigenic alterations in both major surface glycoproteins. Depending on population susceptibility and perhaps changes in the virus, one or more waves, sometimes with increased severity, may follow the initial one. As the level of immunity in the population increases, antigenic drift within the subtype may cause repeated epidemics in subsequent years, and excess mortality in persons younger than age 65 may continue for some years. For example, the pandemic 2009 H1N1 virus has continued to cause fatal infections at least 10 years after its initial emergence.

Zoonotic Influenza

Zoonotic infections may be acquired from swine, poultry, or rarely other animals. Although most avian influenza viruses do not cause infections directly in humans, zoonotic infections due to avian H5, H7, H9, and rarely other subtypes continue to cause outbreaks in regions where human and poultry live in close proximity (e.g., chicken farming, wet markets), thereby representing potential pandemic threats. Initially recognized by a cluster of human cases in Hong Kong in 1997, an epizootic of avian H5N1 infections has affected poultry in many areas of Asia, the Middle East, Europe, and Africa and continues to cause sporadic human illnesses with high mortality and occasional instances of nonsustained human-to-human transmission. From 2013 to 2017, repeated waves of zoonotic avian H7N9 infections have occurred during winter and early spring in China, with case-fatality rates of approximately 35% among hospitalized patients. This virus continues to evolve genetically, thereby leading to variants with altered antigenicity and increased virulence for birds and possibly humans.

In the United States infrequent zoonotic infections have been recognized for decades in people exposed to swine. Since 2012, reassortant swine H3N2 viruses that acquired the M gene and sometimes other genes from the pandemic 2009 H1N1 virus (designated variant H3N2, or H3N2v) have caused hundreds of sporadic infections, particularly in the context of agricultural fairs, sometimes followed by limited human-to-human transmission and serious infections. Other variant swine-origin viruses (H1N1v, H1N2v) have also caused zoonotic infections.

PATHOBIOLOGY

Influenza virus infection is transmitted from person to person by virus-containing respiratory secretions. Large-droplet and small-particle aerosols traveling over a short range (generally within 2 meters) appear to be the predominant route of transmission; longer-range airborne transmission may also occur rarely under unique conditions (e.g., aerosol-generating medical procedures). Other routes, including hand contamination from secretion-laden fomites followed by self-inoculation into the eye or nose, may also contribute. Infection by avian viruses can occur after direct contact with infected birds or their excreta, exposure to contaminated environments and infectious aerosols, ingestion of inadequately cooked food, and sometimes by inoculation into the conjunctiva.

The cellular receptor binding patterns and tissue tropism of influenza viruses are key determinants in transmissibility and pathogenesis. Efficient virus transmission between humans depends largely on virus attachment to and replication in cells bearing α-2,6-linked sialosaccharides in the upper respiratory tract and tracheobronchial tree. By comparison, the α-2,3-linked sialosaccharides, which are higher-affinity binding receptors for avian viruses, are distributed mostly in the distal bronchioles, alveoli, and conjunctiva. Once the virus initiates infection of the respiratory tract epithelium, successive cycles of viral replication infect large numbers of cells and result in destruction of respiratory epithelium and sometimes pneumocytes through direct cytopathic effects or apoptosis.

The incubation period averages 2 days and varies from about 1 to 4 days for seasonal influenza but may be up to 1 week and possibly longer in infections caused by avian viruses. The quantity and duration of virus replication in the respiratory tract generally correlate with the severity of illness and levels of host pro-inflammatory cytokine-chemokine responses. Rapid innate cellular responses are induced through toll-like receptors and retinoic acid inducible

gene I (*RIG-1*) that detect viral RNA and lead to the production of cytokines and interferons (IFNs). Elevated levels of mediators (e.g., IFN-α, interleukin [IL]-6, IL-8, monocyte chemoattractant protein-1 [MCP-1], macrophage inflammatory protein [MIP]–1β, and tumor necrosis factor [TNF]–α), which are frequently detected in blood and respiratory secretions, contribute to systemic symptoms, including fever, and tissue injury.[3] Deficient IFN responses have been associated with severe influenza disease.

The duration of viral replication depends on age, immune status, underlying conditions, and the viral strain. In seasonal influenza, viral RNA generally can be detected in the upper respiratory tract for 3 to 5 days in adults but for longer (7 to 10 days) in the elderly and hospitalized patients, and viral RNA may persist for weeks to months in immunocompromised hosts. By comparison, viral detection by culture, which may better reflect infectivity, is shorter. Patients who suffer from influenza pneumonia appear to have higher viral levels and more prolonged viral replication in their lower respiratory tracts. Viremia or extrapulmonary dissemination (e.g., CNS, GI) may occur in serious avian or pandemic virus infections. Detection of viral RNA in the blood is associated with a poorer prognosis in immunocompromised patients.

Nasal and bronchial biopsy specimens from persons with uncomplicated influenza reveal desquamation of the ciliated columnar epithelium and loss of cilia. The lungs in fatal influenza may show necrotizing bronchitis, diffuse alveolar damage with epithelial necrosis, alveolar edema and hemorrhage, and hyaline membrane formation, followed later by squamous metaplasia and fibrosis. Secondary bacterial infections (e.g., *Staphylococcus aureus, Streptococcus pneumoniae* [Chapter 268], *Streptococcus pyogenes* [Chapter 269]) develop as a result of altered bacterial flora, damage to bronchial epithelium with depressed mucociliary clearance, decreased polymorphonuclear and alveolar macrophage functions, accumulation of alveolar fluid, and suppression of other host immune responses.

Adaptive humoral and cell-mediated responses are important for immunity to influenza. Humoral immunity to natural influenza virus infections appears to be strain specific and largely subtype dependent. A child's first influenza A infection results in immune memory for that viral strain and its related HA subtypes within the same group ("immune imprinting"); subsequent infections or immunizations reinforce the antibody responses, which could contribute to protection against related subtypes (e.g., initial H3N2 infection reducing the risk of H7N9 illness, which is also a group 2 virus). Vaccine-induced immunity is highly strain-specific and typically short-lived (about 6 months), thereby explaining the need for annual update and administration. Protective immunity is mediated by neutralizing antibodies; the generally accepted correlates are serum-neutralizing antibody titers of 1:8 or greater, nasal-neutralizing antibody titers of 1:4 or greater, or an associated increase in the serum HAI titers of 1:40 or greater. However, considerable variability can be seen with the viral strain, in part based on the patient's age,[4] and immune status.[5] Type-specific cell-mediated immunity, which involves CD4+ and CD8+ T-lymphocytic responses, is important for the termination of viral replication and limitation of the infection. Increasing evidence suggests that human genetic factors, such as polymorphism of genes that regulate immune responses, play a role in determining the severity of influenza infection, especially in the immunologically naïve hosts. Examples include polymorphisms in the IFN-induced transmembrane 3 (*IFITM3*) protein, TMPRSS2 protease, CD55 and C1QBP complement-pathway, and SFTPA2 surfactant protein genes.

CLINICAL MANIFESTATIONS

Influenza Syndrome

An abrupt onset of feverishness, chilliness, rigors, headache, myalgia, and malaise is characteristic of influenza but occurs in less than two thirds of cases. Systemic symptoms predominate initially, and prostration occurs in more severe cases. Myalgia, arthralgia, malaise, and headache are usually the most troublesome early symptoms, and their severity is generally related to the level of fever.[6] Ocular symptoms, including photophobia, tearing, burning, and pain on moving the eyes, are sometimes present. Conjunctivitis is characteristic in some avian H7 virus infections, although not in recent zoonotic H7N9 cases. Respiratory symptoms, particularly dry cough and nasal discharge, are typical early in the illness but are overshadowed by the systemic symptoms. Nasal obstruction, hoarseness, and sore throat are likewise common. Pandemic 2009 H1N1 and avian influenza illness are associated with nausea, vomiting, and diarrhea in some adults. As systemic illness diminishes, respiratory complaints and findings become more apparent. Cough, which is the most frequent and troublesome symptom, may be accompanied by substernal discomfort or burning. Cough, lassitude, and malaise may persist for several weeks before full recovery.

Fever, a classic symptom of influenza, usually rises rapidly to a peak of 38° to 40° C within 12 hours of onset, concurrently with systemic symptoms. Fever in adults typically persists for about 3 days, but it may persist for only 1 day or for 5 or more days. Small, tender cervical lymph nodes are often present. Transient scattered rhonchi or localized areas of rales are found in less than 20% of cases.

Symptoms are more frequent and severe in smokers. Among elderly and immunosuppressed patients, particularly recipients of stem cell and solid organ transplants, fever and clinical symptoms initially may be minimal to absent. Despite the paucity of presenting symptoms, however, such patients may progress to severe lower respiratory tract disease. Older adults may less frequently have fever but more commonly have altered mental status and pulmonary complications. In zoonotic infections due to avian H5N1 or H7N9 viruses, upper respiratory complaints are less frequent, gastrointestinal complaints are more common, and progressive viral pneumonia with high mortality is much more likely. Influenza C virus generally causes sporadic upper respiratory tract illness or febrile bronchitis.

Persons at higher risk for influenza-associated complications and hospitalization (Table 332-1) include pregnant women (especially during the second and third trimesters or early postpartum period), morbidly obese patients, immunosuppressed persons, and patients with various comorbid diseases. Most adults hospitalized with seasonal influenza have exacerbations of any underlying cardiopulmonary (e.g., myocardial ischemia, heart failure, chronic obstructive pulmonary disease) or metabolic (e.g., diabetes) conditions, and about one third have pneumonia.

Respiratory Complications

Three pneumonic syndromes have been described—primary influenza viral pneumonia, secondary bacterial pneumonia, and mixed viral and bacterial pneumonia (Chapter 85)—but their clinical presentations and courses overlap considerably. Other common respiratory tract complications include exacerbations of chronic bronchitis, asthma, or cystic fibrosis; croup and bronchiolitis in young children; and otitis media and sinusitis. Bacterial tracheitis can occur, but otherwise uncomplicated influenza tracheobronchitis and airway hyperactivity can persist for weeks.

Severe primary influenza viral pneumonia and associated acute respiratory distress syndrome (ARDS [Chapter 90]) are uncommon during seasonal epidemics but account for 20 to 50% of pneumonias in hospitalized patients during pandemics. ARDS has been the principal manifestation of severe pandemic 2009 H1N1 or avian H5N1 and H7N9 infections. Severe viral pneumonia occurs predominantly in persons with underlying pulmonary and cardiac disorders, pregnancy, or immunodeficiency states,[7] although up to 25 to 40% of pandemic H1N1 and most H5N1 cases have no recognized underlying condition. After a typical onset of influenza, patients develop progressive cough, dyspnea, sometimes hemoptysis, and even cyanosis within 3 to 7 days. Bilateral pulmonary infiltrates and hypoxemia may evolve rapidly.

In patients with classic bacterial superinfection, clinical improvement for 1 to 4 days may be followed by recrudescence of fever, increased cough, sputum production, pleuritic chest pain, and a localized area of consolidation. Secondary pneumonias caused by a range of nosocomial bacterial pathogens are common in patients who are hospitalized with influenza, particularly patients who require mechanical ventilation. Staphylococcal infections may be particularly virulent and cause necrotizing pulmonary lesions. Use of high-dose corticosteroids appears to be a risk factor for bacterial suprainfection, invasive aspergillosis (Chapter 311), and increased mortality.

Nonrespiratory Complications

Severe influenza, including both pandemic 2009 H1N1 and avian H5N1 or H7N9 disease, may be associated with sepsis syndrome (Chapter 94), acute renal insufficiency (Chapter 106), and multiorgan failure. Lymphopenia and thrombocytopenia are common in severe influenza; hemophagocytic syndrome and disseminated intravascular coagulation (Chapter 161) can occur. Myositis with tender leg muscles and elevated serum creatine kinase levels is uncommon in adults, but rarely rhabdomyolysis (Chapter 99) can be severe and cause myoglobinuria. Pregnant women have increased risk of premature labor and spontaneous abortion. Toxic shock syndrome (Chapter 267) caused by respiratory tract infection with toxin-bearing *Staphylococcus aureus* or *Streptococcus pyogenes* can occur, and outbreaks of meningococcal infection (Chapter 274) have been associated with both influenza A and B virus infections. Myocarditis (Chapter 47) or pericarditis (Chapter 62) occurs uncommonly but can be severe.[8] Neurologic complications include aseptic meningitis (Chapter 381), myelitis (Chapter 380), encephalopathy (Chapter 383), necrotizing encephalitis, postinfluenzal Guillain-Barré syndrome (Chapter 388), or immune-mediated encephalitis or cerebellitis. Reye syndrome (Chapter 136), which is a well-recognized hepatic and central

TABLE 332-1 USE OF INFLUENZA VACCINE IN SPECIAL POPULATIONS AND SITUATIONS

When vaccine supply is limited, vaccination efforts should focus on delivering vaccination to persons at higher risk for influenza-related complications listed below as well as these persons:

POPULATIONS AT HIGHER RISK FOR MEDICAL COMPLICATIONS ATTRIBUTABLE TO SEVERE INFLUENZA

- All children aged 6 through 59 months;
- All persons aged ≥50 years;
- Adults and children who have chronic pulmonary (including asthma) or cardiovascular (except isolated hypertension), renal, hepatic, neurologic, hematologic, or metabolic disorders (including diabetes mellitus);
- Persons who are immunocompromised owing to any cause (including immunosuppression caused by medications or by HIV infection);
- Women who are or will be pregnant during the influenza season;
- Children and adolescents (aged 6 months through 18 years) who are receiving aspirin- or salicylate-containing medications and who might be at risk for experiencing Reye syndrome after influenza virus infection;
- Residents of nursing homes and other long-term care facilities;
- American Indians/Alaska Natives; and
- Persons who are extremely obese (BMI ≥40).

PERSONS WHO LIVE WITH OR CARE FOR PERSONS AT HIGHER RISK FOR INFLUENZA-RELATED COMPLICATIONS

- Health care personnel, including physicians, nurses, and other workers in inpatient and outpatient care settings, medical emergency-response workers (e.g., paramedics and emergency medical technicians), and employees of nursing home and long-term care facilities who have contact with patients or residents, and students in these professions who will have contact with patients;
- Household contacts (including children) and caregivers of children aged ≤59 months (i.e., aged <5 years) and adults aged ≥50 years, particularly contacts of children aged <6 months; and
- Household contacts (including children) and caregivers of persons with medical conditions that put them at high risk for severe complications from influenza.

IMMUNOCOMPROMISED PERSONS

- LAIV should be avoided in immunocompromised patients.
- Studies suggest improved immunogenicity with the use of high-dose influenza vaccine.

PERSONS WITH A HISTORY OF GUILLAIN-BARRÉ SYNDROME FOLLOWING INFLUENZA VACCINATION

A history of Guillain-Barré syndrome within 6 weeks following a previous dose of any type of influenza vaccine is considered a precaution to vaccination. Persons who are not at high risk for severe influenza complications and who are known to have experienced Guillain-Barré syndrome within 6 weeks of a previous influenza vaccination generally should not be vaccinated. Seasonal chemoprophylaxis is an option in such persons. However, the benefits of influenza vaccination might outweigh the risks for certain persons who have a history of Guillain-Barré syndrome and who also are at high risk for severe complications from influenza.

PERSON WITH A HISTORY OF EGG ALLERGY

For persons who report a history of egg allergy:

- Persons with a history of egg allergy who have experienced only urticaria (hives) after exposure to egg should receive influenza vaccine. Any licensed, recommended, and age-appropriate influenza vaccine (i.e., any IIV, RIV4, or LAIV4) that is otherwise appropriate for the recipient's health status may be used.
- Persons who report having had reactions to egg involving symptoms other than urticaria (hives), such as angioedema, respiratory distress, lightheadedness, or recurrent emesis; or who required epinephrine or another emergency medical intervention, may similarly receive any licensed, recommended, and age-appropriate influenza vaccine (i.e., any IIV, RIV4, or LAIV4) that is otherwise appropriate for their health status. If a vaccine other than ccIIV4 or RIV4 is used, administration should be done in an inpatient or outpatient medical setting (including but not necessarily limited to hospitals, clinics, health departments, and physician offices). Vaccine administration should be supervised by a health care provider who is able to recognize and manage severe allergic reactions.
- A previous severe allergic reaction to influenza vaccine, regardless of the component suspected of being responsible for the reaction, is a contraindication to future receipt of the vaccine.

Whenever possible, a vaccine recipient should be observed for 15 minutes following administration of any vaccine.

BMI = body mass index; HIV = human immunodeficiency virus; IIV = inactivated influenza vaccine; LAIV = live-attenuated influenza vaccine; RIV = recombinant influenza vaccine.

Modified from Grohskopf LA, Alyanak E, Broder KR, et al. Prevention and control of seasonal influenza with vaccines: recommendations of the Advisory Committee on Immunization Practices—United States, 2020-2021 influenza season. *MMWR Recomm Rep*. 2020;69:1-24.

nervous system complication of influenza A and B virus infections seen in children but rarely in adults, is associated with salicylate use.

DIAGNOSIS

Clinical

In an individual case, influenza often cannot be distinguished from infection with other respiratory viruses or bacterial pathogens that produce similar clinical manifestations (Chapters 84 and 397). Conversely, when public health authorities report an epidemic of influenza in a given community and an ambulatory adult patient is seen with typical febrile respiratory illness, these symptoms likely are caused by an influenza A or B virus infection. In such circumstances, the presence of fever and cough has a positive predictive value as high as 80% for laboratory-proven influenza. However, the predictive value of influenza-like illness in hospitalized patients is much lower. During evaluation, patients should also be asked about recent travel and exposures to ill persons, poultry, swine, and their environments. A positive travel history should prompt a review of the potential presence of novel or emerging respiratory viruses in the region. If risk factors for zoonotic influenza are present, specific laboratory testing is available through most health departments. When other respiratory viruses, particularly SARS-CoV-2 (Chapter 336), are also circulating, diagnostic testing is recommended to optimize management.

Laboratory

Gram staining of sputum may show abundant polymorphonuclear leukocytes but scant bacterial flora. Sputum and endotracheal aspirates usually yield high titers of influenza virus detectable by rapid (less than 60 minutes) nucleic acid amplification testing (NAAT) with a sensitivity of 92 to 95% and a specificity of >98%.[9,10] Multivirus NAAT assays that can simultaneously detect influenza A and B virus, H1, respiratory syncytial virus, rhinoviruses, parainfluenza viruses, coronaviruses,[11] and other viruses are now available to facilitate diagnosis of common pathogens when multiple viruses are circulating.[12] Viral culture, which is less sensitive than NAAT, and serologic studies are rarely useful for clinical care.

In patients who have secondary bacterial infections, Gram staining and culture of sputum or blood cultures most often reveal *Streptococcus pneumoniae* (Chapter 268), *Staphylococcus aureus* (Chapter 267) including community-acquired methicillin-resistant *S. aureus, Haemophilus influenzae* (Chapter 277), or *Streptococcus pyogenes*. NAAT can help determine the specific bacterial pathogen rapidly (Chapter 85). In hospitalized patients, a low serum procalcitonin level may help discriminate viral from mixed influenza-bacterial pneumonia and reduce antibiotic use (Chapter 85).[A1]

PREVENTION

Vaccination

Annual influenza immunization is recommended for all persons aged 6 months or older in the United States (Chapter 15).[13] Persons at higher risk for influenza-related complications or who care for or are exposed to them remain particular priorities of immunization efforts (see Table 332-1), especially when vaccine delays or shortages occur. Influenza vaccine policies differ across countries. Because influenza immunization benefits both mother and infants, the World Health Organization (WHO) has ranked pregnant women as the highest priority, followed (in no particular order) by health care workers, children 6 to 59 months of age, the elderly, and individuals with high-risk conditions.

Seasonal vaccine should be given each year in the fall as soon as available, preferably by October before the influenza season in northern temperate

areas. Quadrivalent vaccines with two A (H1N1, H3N2) and two B lineage (Yamagata, Victoria) antigens are preferred over trivalent vaccines because of their better breadth of coverage.

Egg-grown, intramuscularly administered inactivated influenza vaccines for persons 6 months of age and older; a high-dose inactivated vaccine and an MF-59 adjuvanted inactivated vaccine for persons aged 65 years and older; and a live-attenuated intranasal vaccine for otherwise healthy persons aged 2 to 49 years are currently licensed in the United States (E-Table 332-3). A mammalian cell culture–grown inactivated vaccine and a recombinant DNA–produced HA vaccine, particularly useful in individuals who have severe egg allergy, are also approved for seasonal use.

Racial and ethnic disparities in influenza vaccination rates persist,[14] and rates for key target groups, including pregnant women and health care workers, remain suboptimal. Immunization of health care personnel, which represents an important patient safety issue, can be enhanced by strategies to improve access, and especially by employer mandates.

Inactivated vaccines (Chapter 15) given by intramuscular injection provide about 50 to 70% protection against seasonal influenza illness in healthy adults,[1S] albeit with substantial year-to-year variations in effectiveness,[A2] and often much lower effectiveness in H3N2 seasons. Immunization reduces work absenteeism, use of health care resources, and antibiotics when the vaccine is well matched to the epidemic strain. On average, the effectiveness of the vaccination seems to decline by about 7% per month for at least 6 months after vaccination.

Immunogenicity and hence protection rates with inactivated seasonal vaccines are lower in elderly persons, particularly infirm nursing home residents, in immunosuppressed patients, and during circulation of H3N2 viruses. The effectiveness of influenza vaccine for prevention of medically attended acute respiratory illness among the elderly in nursing homes is estimated to average 20 to 40%. In ambulatory high-risk patients, immunization reduces hospitalizations from pneumonia, influenza, and major cardiovascular events as well as all-cause mortality during the influenza season. Both higher-dose inactivated vaccines (four-fold or three-fold more HA per strain) and adjuvanted inactivated vaccine are more immunogenic and protective than standard vaccine against seasonal influenza illness in older ambulatory adults and are the preferred vaccine for these individuals.[A3] High-dose vaccine also results in improved protection among kidney transplant patients.[A4] Immunization of children appears to reduce respiratory illness in household and community contacts.[A5] Immunization of health care providers reduces the risk of transmission to patients as well as their own risk of infection.

Experimental vaccines are using novel vaccine delivery approaches (i.e., mRNA) or alternative targets (hemagglutinin stem, neuraminidase, matrix protein 2 or nucleoprotein) with the goal of enhanced production and improving efficacy.[16] The holy grail of this effort is to develop a universal influenza vaccine that can provide coverage against a range of viruses for more than 1 year.[A6,A7]

With inactivated vaccine, fever and systemic symptoms occur at rates comparable to those of adults given placebo but are more common in young children. Among adults, 25% or more may have mild local reactions at the site of injection. Intranasal vaccine causes coryza and sore throat in adults.

Hypersensitivity reactions to residual egg proteins or other vaccine components occur rarely, and any licensed vaccine can be given to the patient. However, use of vaccines other than ccIIV4 or RIV4 should be given in a monitored clinical setting. Inactivated vaccine does not cause exacerbation of asthma but may be rarely associated with Guillain-Barré syndrome in older adults.

Medications for Chemoprophylaxis

Oral oseltamivir, single-dose baloxavir (40 mg if <80 kg [176 pounds], 80 mg if >80 kg [176 pounds]),[A8] and inhaled zanamivir are effective for chemoprophylaxis of both influenza A and B virus infections, including postexposure prophylaxis in households (Table 332-2), with each reducing the risk of symptomatic influenza infections by about 60 to 85%.[17] When an outbreak develops, unimmunized high-risk persons can be given such chemoprophylaxis and inactivated vaccine simultaneously, with cessation of chemoprophylaxis after 14 days. Alternatively, if vaccine is not available or contraindicated, is a poor match, or if the patient is highly immunosuppressed, chemoprophylaxis may be continued for the duration of the community outbreak. When given to patients and staff alike, these drugs are also helpful in managing nosocomial outbreaks.

Therapeutic doses (i.e., twice daily) should be considered for postexposure prophylaxis in immunocompromised hosts. Despite demonstrable efficacy, however, most public health authorities do not advise routine use of antiviral chemoprophylaxis, largely because of concerns regarding promotion of antiviral resistance and drug availability. In the community setting, an alternative approach is close monitoring and early initiation of antiviral treatment after suspected influenza exposures. Chemoprophylaxis is generally not recommended if more than 2 to 3 days have elapsed since exposure to a person with seasonal influenza.

Precautions

On entry to a health care facility, source control (e.g., face mask placement) and instruction in respiratory hygiene and cough etiquette should be implemented for symptomatic patients. Patients hospitalized with suspected or proven influenza should be managed with standard and droplet precautions and, when possible, private rooms. Face masks appear to provide equivalent protection compared with N95-type respirators in the outpatient setting,[A9] but compliance with a properly fitted N95-type respirator should provide better protection in the inpatient setting. An N95-type respirator should be used with other precautions (including gloves, gown, and eye protection with face shield or goggles; an airborne infection isolation room) during aerosol-generating procedures.

Early implementation and compliance with masks and hand hygiene appear to reduce the risk of secondary infections somewhat in household contacts. Physical distancing, masking, and other nonpharmaceutical interventions adopted for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2; Chapters 335 to 337) have led to marked reductions in the circulation and impact of the influenza virus in many countries.

The risk of zoonotic infections can be reduced by avoiding exposure to potentially infectious poultry or swine and their environments. Travelers to affected countries should avoid visiting live bird markets, practice frequent hand hygiene, and not eat inadequately cooked poultry products. Closure of live bird markets and mass immunization of poultry using bivalent vaccines (to H7 and H5) have been associated with marked decrease in human cases since 2018.

TREATMENT

Hospitalized Patients

Antiviral treatment (see Table 332-2) is recommended as soon as possible for patients who have proven or suspected influenza and who manifest severe, complicated, or progressive illness; are hospitalized; or have underlying conditions that increase the risk for complications (see Table 332-1), including adults older than age 64 years and children younger than age 5 years.[18] In patients who have serious illness or high-risk conditions, decisions about initiating antiviral therapy should not wait for laboratory confirmation of influenza. Adults admitted with community-acquired pneumonia (Chapter 85) during the influenza season should initially receive both early antiviral therapy[19] and antibiotics, with subsequent therapy guided by NAAT and microbiologic testing. Although initiation of therapy is most effective if started within 2 days of the onset of symptoms, initiation within 6 hours of hospital admission is associated with reduced length of stay and death.[20]

Oral baloxavir[A10] and intravenous formulations of peramivir and zanamivir provide reliable delivery of high drug levels in seriously ill persons.[A11] A single dose of peramivir[A12] appears to be as effective as a 5-day regimen of oseltamivir in treating uncomplicated influenza, but daily dosing is advised in hospitalized patients. Intravenous zanamivir is approved for use in Europe and is available for compassionate use in a very limited number of countries, but is no more effective than oral oseltamivir in hospitalized patients with influenza.[A13]

Double doses of oseltamivir and/or combinations of anti-influenza drugs[21] do not appear to be more clinically effective than standard doses, although they may clear influenza viruses more rapidly[A14,A15] and reduce the risk of resistance during the course of therapy. Longer courses (e.g., 10 days) and perhaps higher doses are warranted in critically ill patients and immunocompromised hosts, in whom monitoring for virologic clearance is warranted.

During therapy, the emergence of resistance to oseltamivir is infrequent but highlights the need for ongoing susceptibility monitoring in high-risk patients with persistent symptomatic viral shedding after 5 to 7 days of treatment. Resistance during the course of baloxavir therapy is more common, occurring in about 10% of adults.[22] Zanamivir is inhibitory for most oseltamivir-resistant variants, and, if available, intravenous zanamivir, especially if combined with baloxavir, is generally preferred for treating severe infections that are suspected or proven to be oseltamivir-resistant.

Fulminant influenza viral pneumonia, particularly following pandemic 2009 H1N1 or avian influenza infection, requires intensive care, including ventilatory support (Chapter 91), often renal replacement therapy, and sometimes extracorporeal membrane oxygenation. Adding systemic corticosteroids for influenza-associated pneumonia or ARDS has been associated with prolonged viral replication, adverse effects including secondary bacterial infections, and increased mortality, so their routine use should be avoided.

Outpatients

Treatment with oseltamivir or single-dose baloxavir within 2 days of the onset of symptoms also may be considered in low-risk outpatients with uncomplicated febrile illness, in whom therapy reduces the duration of symptoms by 1 to 2 days, the time to functional recovery, the risk for pneumonia and hospitalization,[A16]

E-TABLE 332-3 CURRENTLY APPROVED INFLUENZA VACCINES IN THE UNITED STATES (2020-2021 SEASON)*

VACCINE TYPE	SUBSTRATE FOR PRODUCTION	NO. COMPANIES	FDA-APPROVED AGE RANGE (yr)	ROUTE	DOSE IN ADULTS
Inactivated influenza vaccine, quadrivalent, standard dose (SD-IIV4)	Eggs	Multiple	≥0.5†	IM	0.5 mL containing 15 µg per HA antigen
Adjuvanted inactivated influenza vaccine, quadrivalent, adjuvanted (aIIV4)	Eggs	1	≥65	IM	0.5 mL containing 15 µg per HA antigen
Inactivated influenza vaccine, quadrivalent, high-dose (HD-IIV4)	Eggs	1	≥65	IM	0.7 mL containing 60 µg per HA antigen
Inactivated influenza vaccine, trivalent, cell culture (ccIIV3)	MDCK cells	1	≥18	IM	0.5 mL containing 15 µg per HA antigen
Inactivated influenza vaccine, quadrivalent, cell culture (ccIIV4)	MDCK cells	1	≥18	IM	0.5 mL containing 15 µg per HA antigen
Recombinant inactivated influenza vaccine, quadrivalent (rIV4)	Insect cells	1	≥18	IM	0.5 mL containing 45 µg per HA antigen
Live-attenuated influenza vaccine, quadrivalent (LAIV4)‡	Eggs	1	2-49‡	Intranasal	0.2 mL by prefilled single-use intranasal sprayer

*Package inserts for U.S.-licensed vaccines are available at http://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm093833.htm.

†Lower age limit of approval depends on specific vaccine product.

‡LAIV is approved only for otherwise healthy nonpregnant persons. It should be avoided in close contacts and caregivers of severely immunosuppressed persons who require a protected environment and in children and adolescents receiving concomitant aspirin therapy.

aIIV3 = adjuvanted inactivated influenza vaccine trivalent; ccIIV3 = cell culture inactivated influenza vaccine trivalent; ccIIV4 = cell culture inactivated influenza vaccine quadrivalent; HA = hemagglutinin; IIV3 = inactivated influenza vaccine trivalent; IIV4 = inactivated influenza vaccine quadrivalent; IM = intramuscular; LIV4 = live attenuated influenza vaccine quadrivalent; MDCK = Madin-Darby canine kidney; rIIV3 = recombinant inactivated influenza vaccine trivalent; rIIV4 = recombinant inactivated influenza vaccine quadrivalent.

TABLE 332-2 ANTIVIRAL DOSE RECOMMENDATIONS IN ADULTS

DRUG	ROUTE	TREATMENT	PROPHYLAXIS	DOSE REDUCTIONS	COMMENT
Baloxavir	Oral	80 or 40 mg single dose in uncomplicated illness	80 or 40 mg single dose for post-exposure prophylaxis	Weight-based dosing	Inhibitory for NAI- and adamantane-resistant viruses
Oseltamivir	Oral	75 mg bid	75 mg once daily†	CrCl ≤60 mL/min	Gastrointestinal and (very uncommonly) CNS side effects
Zanamivir	Inhaled	10 mg bid	10 mg once daily†	Avoid in those with underlying airway disease	Training in use of the inhaler device is important
Peramivir*	Intravenous	600 mg single IV dose in uncomplicated illness	Not studied	CrCl <50 mL/min	Single dose approved for uncomplicated influenza in adults in the United States
Laninamivir*	Inhaled	40 mg once in uncomplicated illness (Japan)	20 mg once daily for 2 days (Japan)	Avoid in those with underlying airway disease	Currently investigational in the United States; approved in Japan
Zanamivir*	Intravenous	600 mg q12h	Not studied	CrCl <80 mL/min	Currently investigational in the United States
Favipiravir*	Oral	1600 mg twice on day 1; 1600 mg bid (Japan) on days 2-5	Not studied	Teratogenic; avoid in pregnancy	Approved in Japan but investigational in the United States; inhibitory for NAI- and adamantane-resistant viruses; teratogenic
Amantadine	Oral	100 mg bid	100 mg bid	Age >64 yr, CrCl <50-80 mL/min	Gastrointestinal and CNS side effects Currently circulating strains are resistant
Rimantadine	Oral	100 mg bid	100 mg bid	Age >64 yr, CrCl <10 mL/min, or severe hepatic dysfunction	Lower risk of CNS side effects than with amantadine Currently circulating strains are resistant

*Oral favipiravir is approved in Japan but only for treating novel or reemerging influenza infections when other drugs are ineffective or not sufficiently effective; higher-dose regimens are being studied in the United States.

†Full therapeutic doses for postexposure prophylaxis (i.e., twice-daily dosing) are appropriate for infections due to novel influenza viruses and in immunocompromised hosts.

The standard duration of treatment in uncomplicated illness is 5 days, except for baloxavir or IV peramivir, for which single doses suffice. A longer treatment duration (e.g., 10 days) should be considered for infections in seriously ill patients, immunosuppressed hosts, or infections caused by novel viruses. Higher doses (e.g., 150 mg or 225 mg twice daily) of oseltamivir have been used in patients with serious lower respiratory illness, immunocompromise, or infections by novel viruses. The duration of prophylaxis depends on the epidemiologic setting; durations of 2 weeks after immunization or 7 to 10 days for postexposure prophylaxis are appropriate. Antiviral prophylaxis may interfere with response to intranasal live-attenuated vaccine but not to intramuscular inactivated vaccine.

bid = twice daily; CNS = central nervous system; CrCl = creatinine clearance; IV = intravenous; NAI = neuraminidase inhibitor.

and the risk for respiratory complications that lead to antibiotic use.[A17] Baloxavir appears to be the more effective option for patients with influenza B.[A18,A19]

Inhaled zanamivir may be infrequently associated with bronchospasm, sometimes severe, and nebulization of the lactose-containing commercial form is contraindicated in intubated patients. Oseltamivir is associated with nausea, vomiting, rash, and possibly rare neuropsychiatric symptoms.

Symptomatic measures include antipyretics and cough suppressants. Salicylates should not be used, especially in children younger than age 16 years, because of their association with Reye syndrome.

PROGNOSIS

Most influenza patients make a full recovery, but they may require several weeks to return to their premorbid functional status. If disease progresses despite 5 to 7 days of antiviral therapy, genotypic assays can identify drug resistance. The risk of acute myocardial infarction is increased more than six-fold in the first 7 days after diagnosis.[23] Influenza in elderly persons can cause prolonged loss of function and impairment of activities of daily living.

Approximately 90% of seasonal influenza-related deaths occur in persons who are older than 65 years or at high risk because of comorbid conditions. Mortality occurs in about 5 to 10% of adults hospitalized with seasonal influenza but is as high as 40 to 60% in zoonotic H5N1 and H7N9 infections. Bacterial infections (Chapter 85) are associated with about 20 to 40% of deaths. Detection of viral RNA in the blood is a poor prognostic finding that may reflect high viral burden in the lower respiratory tract. Once viral pneumonia progresses to respiratory failure, the mortality rate is often 50% or higher, but the risk is reduced by early antiviral therapy and high-quality intensive care.

333 ADENOVIRUS DISEASES

MICHAEL G. ISON

DEFINITIONS

Human adenoviruses, which are members of the Adenoviridae family and the *Mastadenovirus* genus, are divided into seven species (A, B, C, D, E, F, and G; Table 333-1). Modern sequencing and molecular diagnostics have identified over 80 serotypes. Adenoviruses are double-stranded DNA, nonenveloped viruses that code for 20 early and 15 late proteins. The knobbed fiber protrudes from the fiber base (Fig. 333-1).

EPIDEMIOLOGY

Adenoviruses cause a range of infections from mild self-limited respiratory viral infections, conjunctivitis, and diarrhea to severe disseminated disease.[1] Adenoviruses have a worldwide distribution, and infections occur throughout the year without significant seasonal variability. Most infections occur as sporadic events, although local or regional epidemics have been described. Asymptomatic respiratory infection is common and is associated with prolonged carriage, particularly in feces and tonsillar tissue. Most patients with adenovirus infection are children, generally younger than 5 years, and most individuals have serologic evidence of exposure to adenovirus by age 10. Only about 25% of symptomatic cases occur in adults.[2] Adenoviruses 1, 2, and 5 are most common among children, whereas adenoviruses 3, 4, and 7 are more common in adults.

Severe outbreaks in the United States, including on college campuses, have resulted in cases requiring hospitalization, and nosocomial transmission can cause severe infections in health care workers. Adenovirus is the leading cause of respiratory viral infections among military recruits.[3] Unlike the year-round circulation of adenovirus in civilians, peaks of disease are recognized within the first 4 weeks of training exercises among military recruits. Rates of adenovirus among military recruits declined significantly with widespread use of an oral live-attenuated vaccine in 1971, increased after supplies of vaccine were depleted by 1999, then declined again after an oral live-attenuated adenovirus type 4 and 7 vaccine was approved in 2011 (E-Fig. 333-1).

PATHOBIOLOGY

Adenoviruses enter susceptible hosts by the mouth, nasopharynx, or ocular conjunctiva. The fiber protein of the virus binds to a cellular receptor that varies by serotype. On initial infection, local replication can induce considerable cellular damage owing to tissue invasive infection. Necrotizing bronchitis, bronchiolitis, interstitial pneumonia, and fibrin and hyaline membranes are seen within the alveoli during pulmonary infections. In ocular infections, exudative and mononuclear infiltrates develop beneath the epithelium. Replication results in desquamated epithelial cells, which induce hypertrophy in regional lymphatic tissue and active proliferative germinal centers. This reaction can cause swollen adenoids or intussusception (Chapter 128) associated with enlarged mesenteric lymph nodes, particularly in children.

Components of both the innate and adaptive immune responses are important for the control of adenovirus replication. Alveolar macrophages and Kupffer cells help eliminate adenovirus from the lung and liver and also secrete inflammatory cytokines such as tumor necrosis factor (TNF), interferon (IFN)–γ, interleukin (IL)–1β, IL-6, IL-8, and IL-12. $CD4^+$ and $CD8^+$ T lymphocytes play a particularly important role in the control and clearance of replicating adenovirus in humans, and the absolute lymphocyte and $CD4^+$ T-lymphocyte levels correlate inversely with adenovirus infection and the risk for developing disseminated adenoviral infections in immunosuppressed transplant patients.

Both group- and type-specific neutralizing and non-neutralizing antibodies are produced in response to infection and also play a role in limiting infection. Group-specific antibodies do not neutralize the virus but can confirm infection. Neutralizing antibodies may protect against disease manifestations in the previously infected host or against reinfection with the same serotype, but they do not eliminate the carrier state.

‡Associated with epidemic pneumonia with high mortality rate.
§Associated with epidemics.

CLINICAL MANIFESTATIONS

Adenovirus infections have a wide range of clinical manifestations that are linked to the virus type (see Table 333-1) as well as to the age and immunocompetence of the host. Common syndromes include infections of the respiratory tract, eye, gastrointestinal tract, genitourinary tract, and central nervous system (CNS). Disseminated infection also occurs, especially in immunosuppressed patients. Associations with adenovirus and obesity have been proposed as well.

Respiratory Tract Infections

About 10% of pneumonias in childhood and up to 5% of community-acquired pneumonias in some series of adults may be attributable to adenovirus, with

ABSTRACT

Adenovirus is a double-stranded DNA virus that causes a range of infections from mild, self-limited respiratory viral infections, conjunctivitis, and diarrhea to severe respiratory infections and disseminated disease. Military recruits, children, and the immunocompromised appear to be at greatest risk of more severe disease. Diagnosis is focused on molecular methods, including polymerase chain reaction, combined with pathology for end-organ disease. Treatment is generally supportive. Studies of cidofovir and brincidofovir show activity against adenovirus, but their use is generally limited to immunocompromised patients and patients with life-threatening infections.

KEYWORDS

adenovirus
pneumonia
pharyngoconjunctival fever
epidemic keratoconjunctivitis
diarrhea
hemorrhagic cystitis

adenovirus 7 probably carrying the highest risk for pneumonia.[4] Typical symptoms include nasal congestion, coryza, and cough, which may mimic pertussis infections (Chapter 289). Generalized malaise, fever, chills, myalgia, headache, and abdominal pain are common systemic symptoms.[5] Exudative tonsillitis and cervical adenopathy are also seen. If conjunctivitis accompanies these signs and symptoms, the disease is designated as pharyngoconjunctival fever. Otitis media is a common presentation, particularly among infants under 1 year of age. Cases in children and in adults, especially military recruits, are indistinguishable from other viral respiratory infections such as influenza (Chapter 332), parainfluenza (Chapter 331), and respiratory syncytial virus (Chapter 330). Recent outbreaks of sometimes severe and fatal adenovirus pneumonia have been described[6] and should be kept in the differential in patients with severe pneumonia.

Ocular Infections

The two most common manifestations of ocular adenovirus infection are pharyngoconjunctival fever and epidemic keratoconjunctivitis. Pharyngoconjunctival fever is typically a mild form of acute follicular conjunctivitis that accompanies febrile pharyngitis or cervical adenitis following a 6- to 9-day incubation period and may affect both eyes. Both bulbar and palpebral conjunctival involvement may occur. Swimming pools or lakes are a common source of infection. Symptoms typically resolve without treatment and without sequelae.

Epidemic keratoconjunctivitis is a more serious disease, with edema of the eyelids, pain, lacrimation, and photophobia.[7] Painful corneal opacities may occur, although they typically resolve over time. The disease typically involves just one eye and is self-limited. However, it may rarely result in permanent corneal damage, and large corneal epithelial full-layer detachment can also occur. Recovery may take up to 4 weeks. The disease is highly contagious, including nosocomial transmission to members of the health care team; as a result, diligent infection control is required even in suspected cases.

Gastrointestinal Tract Infection

Adenovirus can infect any part of the gastrointestinal tract and cause fever, nausea, vomiting, and diarrhea. Up to 10% of pediatric cases of diarrhea are caused by adenovirus, often with symptoms persisting for 8 to 12 days. Some adenoviruses can also cause mesenteric adenitis, which may clinically mimic appendicitis and rarely result in intussusception (Chapter 128). Adenovirus inclusions are seen in about one third to one half of appendices removed at surgery.

Genitourinary Tract Infections

Hemorrhagic cystitis, which typically manifests as microscopic or macroscopic blood in the urine and pain and cramping of the bladder, has been reported in children with adenoviruses 11 and 21 infection. Adults can present with urethritis with or without cystitis due to adenoviruses 19 and 37. Both diseases typically resolve over time without intervention.

Other Manifestations of Adenovirus

Acute viral hepatitis (Chapter 134),[8] meningitis (Chapter 381), and encephalitis (Chapter 383) have been reported occasionally in association with adenovirus infection. Adenovirus infection also can cause myocarditis and dilated myocardiopathy (Chapter 47).

A number of studies have found an association between detection of adenovirus in amniotic fluid associated with abnormal fetuses. In particular, echogenic liver lesions with or without hydrops and neural defects in fetuses were more common with patients with adenovirus detected in the amniotic fluid.

Adenovirus Diseases in Immunocompromised Patients

Primary adenovirus infection or reactivation of infection causes a wide range of infectious syndromes in immunocompromised children and adults. In the hematopoietic stem cell transplantation population (Chapter 163), the incidence of disease ranges from 3 to 47%.[9] Risk factors include an allogeneic transplant, T cell–depleted grafts, use of alemtuzumab, and acute graft-versus-host disease. Severe respiratory disease, hepatitis, colitis, hemorrhagic cystitis, and adenoviral keratoconjunctivitis can occur. Severe lymphopenia (<300 cells/μL) is associated with disseminated disease. Although disseminated disease only affects 1 to 7% of hematopoietic stem cell transplantation recipients, it is associated with a significant risk of mortality (8 to 26%).

Among various solid organ transplant recipients, asymptomatic adenovirus viremia is common.[10] However, progression to symptomatic disease is more common in small bowel and liver transplant recipients, pediatric transplant recipients, patients who receive antilymphocyte antibodies, and patients with donor-positive/recipient-negative adenovirus status.[11] Adenoviral hepatitis, typically caused by adenoviruses 1, 2, or 5, is most common among liver transplant recipients and can be diagnosed by detection of viremia or visualization of viral intranuclear inclusions on biopsy. Adenovirus enterocolitis occurs in small bowel transplant recipients and may mimic rejection. Adenoviral pneumonia is associated with graft loss, death, or progression to obliterative bronchiolitis for lung transplant recipients. Adenovirus causes hemorrhagic cystitis with or without interstitial nephritis in kidney transplant recipients. Such patients typically present with fever, hematuria, and new-onset renal dysfunction. Adenovirus DNA in biopsy specimens is associated with worse outcomes among pediatric heart transplant patients.

Primary adenoviral infections can cause severe, frequently fatal disease in children with primary immunodeficiency syndromes, including severe combined immunodeficiency disease (Chapter 231). Fatal cases have been reported in patients with acquired immunodeficiency syndrome (AIDS), but most are self-limited, particularly in patients on highly active antiretroviral therapy or without significant CD4 lymphopenia.

DIAGNOSIS

Diagnosis of adenovirus depends on isolation of the virus from infected tissue and either histopathologic evidence of local replication or clinical symptoms consistent with infection. Detection of virus alone is not diagnostic of an adenovirus disease, because the virus can be latent in some tissues and can be intermittently shed from the throat or in the stool for months to years after primary infection. Quantitative polymerase chain reaction (PCR) has a higher diagnostic yield than culture or direct fluorescent antigen detection. Quantitative PCR assays are also useful to predict progression to disseminated disease in pediatric and, to a lesser extent, adult hematopoietic stem cell transplantation recipients and to determine response due to therapeutic interventions.[12] It is critical to recognize that, particularly in immunocompromised patients and in patients with nonpulmonary disease, use of nasal swabs for detection of adenovirus using one of the many commercially available respiratory viral panel assays may fail to detect adenovirus infection. Testing of relevant specimens (e.g., stool for gastrointestinal disease, urine for urinary tract disease, blood for systemic or disseminated disease, and ocular swabs or fluid for ocular disease) is required for accurate detection of adenovirus.

TREATMENT

No antiviral agents are specifically approved for the treatment of adenovirus. Ribavirin is active in vitro but has not been helpful clinically. Cidofovir, which is a potent inhibitor of adenovirus in cell culture, has been used (preferably at 1 mg/kg three times a week), but data suggest that its ratio of efficacy to toxicity, predominantly nephrotoxicity, is too narrow to be clinically useful, except for severe infections.[13]

Oral brincidofovir, which is also approved for treatment of smallpox (Chapter 343) and is not nephrotoxic, is generally well tolerated and can suppress adenovirus.[A1,A2] The optimal dose of therapy has not been defined, and higher doses are associated with diarrhea that may be pathologically confused with graft-versus-host disease (Chapter 163). A newer approach using adenovirus- and multivirus-specific T cells is also being studied in prospective trials.

PREVENTION

Strict attention to contact and droplet precautions can prevent health care–associated and institutional outbreaks of adenovirus infections, including epidemic keratoconjunctivitis. An oral live-attenuated adenovirus 4 and 7 vaccine is well tolerated, with a vaccine efficacy of 99%. Currently, the vaccine is only indicated and available to U.S. military personnel, ages 17 to 50 years.

PROGNOSIS

Prognosis is strongly linked to immune competence. Immunocompetent patients typically have self-limited illnesses that generally can be managed with symptomatic care, although some epidemics, including adenovirus 7 and 14 epidemics, have resulted in high case-fatality rates. In immunocompromised adults, persistent or rising adenovirus viremia predicts progressive infection; in such cases, a reduction of immunosuppression and institution of antiviral therapy are associated with better outcomes. By comparison, patients with ongoing or predicted recovery of their lymphocyte counts may clear their viremia without specific intervention. Serial monitoring of the adenovirus load can help determine the response to therapy, which is seen in most but not all patients. Failure to reduce the viral load after 2 weeks of therapy portends a poor prognosis.

334 PRE-2019 CORONAVIRUSES

FIONA P. HAVERS, HANNAH KIRKING, AND IAN D. PLUMB

DEFINITION

Human coronaviruses are a frequent cause of respiratory illness. Seasonal human coronaviruses (CoV) 229E, OC43, NL63, and HKU1 generally cause mild, self-limited upper respiratory tract infections (Chapter 329). However, three newer, highly pathogenic coronaviruses have caused major public health challenges: severe acute respiratory syndrome coronavirus (SARS-CoV), which was first identified in 2003; Middle East respiratory syndrome (MERS-CoV), which was identified in 2012; and SARS-CoV-2, which was identified in 2020 and which has caused the coronavirus disease 2019 (COVID-19; Chapters 335 to 337) global pandemic.

The Pathogen

The family Coronaviridae is currently divided into four genera—alpha, beta, gamma, and delta coronaviruses (Fig. 334-1). Human coronaviruses (HCoVs) are currently in two of these genera: alpha coronaviruses (229E and NL63), and beta coronaviruses (HKU1 and OC43). MERS-CoV, SARS-CoV, and SARS-CoV-2 are also beta coronaviruses but belong to different lineages than the common human coronaviruses.[1]

Coronaviruses are single-stranded positive-sense RNA viruses that contain large genomes (27 to 32kb) that can be replicated fully or can be replicated partially via subgenomic RNAs. The coronavirus genome encodes four main structural proteins: spike, membrane, nucleocapsid, and envelope; HKU1 and OC43 genomes also encode a hemagglutinin-esterase protein. Interspersed between the main structural proteins are several accessory proteins that vary among human coronaviruses and interact with the host immune response. Coronavirus genomes also encode a variety of nonstructural proteins that contribute to viral replication, proofreading, and modulation or evasion of the host response.[2]

SEASONAL CORONAVIRUS

EPIDEMIOLOGY

Seasonal coronaviruses 229E, NL63, HKU1, and OC43 are found worldwide. Seroprevalence studies indicate that exposure is common in early childhood and that a majority of adults are seropositive for at least one seasonal coronavirus. Although these viruses have been known to cause infection at any time of the year, in most temperate regions of the northern hemisphere, infections occur primarily in December through March, with peaks in January and February.[3] In a large prospective study in Norway of all hospitalized children aged 16 years or younger with respiratory tract infections, seasonal coronaviruses were present in 9% of patients. Among patients with a seasonal coronavirus, approximately two thirds had co-detection of another respiratory virus. Consistent with other studies, OC43 and NL63 were detected most frequently, with HKU1 and 229E detected much less frequently in the hospitalized patients. OC43 and NL63 infections had clear biennial peaks and alternated with HKU1, which circulated every second year when OC43 and NL63 detection rates were low.[4] By comparison, coronavirus 229E appears to be sporadic. Consistent with these findings, another recent household study showed that the proportion of acute respiratory infections associated with coronaviruses varied from 8 to 16% during annual respiratory virus season, which generally occurs from October through April in the temperate Northern Hemisphere.[5]

The incidence of symptomatic infection is highest in children below age 5 years for all seasonal coronaviruses except 229E, for which the incidence is relatively consistent across age groups. However, multiple studies indicate that all seasonal coronaviruses can infect individuals of all ages and that reinfection is common.[6]

Seasonal coronaviruses are likely spread via direct contact with respiratory droplets, aerosols, or secretions (Table 334-1). Viral shedding can frequently occur beyond 1 week in both symptomatic and asymptomatic adults and children, with viral detection typically persisting for a longer duration in children under age 5 years. Seasonal coronaviruses have a high attack rate within households; the proportion who become infected after exposure to an infected household member ranges from 7.2% for 229E to 12.6% for NL63. As a result, approximately 25% of all infections are likely acquired from an infected household contact. Children are the most frequently identified index case except for 229E, whereas adults ages 18 to 49 years comprise nearly half of the secondarily infected household contacts. Seasonal coronavirus outbreaks associated with significant morbidity have been described in babies in neonatal intensive care units and in adults in long-term care facilities.

PATHOBIOLOGY

Similar to other human coronaviruses, seasonal coronaviruses are thought to have a zoonotic origin (see Table 334-1)[7] and to attach to human cells via the receptor binding domain of the coronavirus spike protein. NL63 binds to angiotensin converting enzyme 2 (ACE-2), the same receptor as SARS-CoV and SARS-CoV-2. By comparison, 229E binds aminopeptidase N, whereas OC43 and HKU-1 bind 9-O-acetylated sialic acid. Although both ACE-2

334 PRE-2019 CORONAVIRUSES

FIONA P. HAVERS, HANNAH KIRKING, AND IAN D. PLUMB

DEFINITION

Human coronaviruses are a frequent cause of respiratory illness. Seasonal human coronaviruses (CoV) 229E, OC43, NL63, and HKU1 generally cause mild, self-limited upper respiratory tract infections (Chapter 329). However, three newer, highly pathogenic coronaviruses have caused major public health challenges: severe acute respiratory syndrome coronavirus (SARS-CoV), which was first identified in 2003; Middle East respiratory syndrome (MERS-CoV), which was identified in 2012; and SARS-CoV-2, which was identified in 2020 and which has caused the coronavirus disease 2019 (COVID-19; Chapters 335 to 337) global pandemic.

The Pathogen

The family Coronaviridae is currently divided into four genera—alpha, beta, gamma, and delta coronaviruses (Fig. 334-1). Human coronaviruses (HCoVs) are currently in two of these genera: alpha coronaviruses (229E and NL63), and beta coronaviruses (HKU1 and OC43). MERS-CoV, SARS-CoV, and SARS-CoV-2 are also beta coronaviruses but belong to different lineages than the common human coronaviruses.[1]

Coronaviruses are single-stranded positive-sense RNA viruses that contain large genomes (27 to 32kb) that can be replicated fully or can be replicated partially via subgenomic RNAs. The coronavirus genome encodes four main structural proteins: spike, membrane, nucleocapsid, and envelope; HKU1 and OC43 genomes also encode a hemagglutinin-esterase protein. Interspersed between the main structural proteins are several accessory proteins that vary among human coronaviruses and interact with the host immune response. Coronavirus genomes also encode a variety of nonstructural proteins that contribute to viral replication, proofreading, and modulation or evasion of the host response.[2]

SEASONAL CORONAVIRUS

EPIDEMIOLOGY

Seasonal coronaviruses 229E, NL63, HKU1, and OC43 are found worldwide. Seroprevalence studies indicate that exposure is common in early childhood and that a majority of adults are seropositive for at least one seasonal coronavirus. Although these viruses have been known to cause infection at any time of the year, in most temperate regions of the northern hemisphere, infections occur primarily in December through March, with peaks in January and February.[3] In a large prospective study in Norway of all hospitalized children aged 16 years or younger with respiratory tract infections, seasonal coronaviruses were present in 9% of patients. Among patients with a seasonal coronavirus, approximately two thirds had co-detection of another respiratory virus. Consistent with other studies, OC43 and NL63 were detected most frequently, with HKU1 and 229E detected much less frequently in the hospitalized patients. OC43 and NL63 infections had clear biennial peaks and alternated with HKU1, which circulated every second year when OC43 and NL63 detection rates were low.[4] By comparison, coronavirus 229E appears to be sporadic. Consistent with these findings, another recent household study showed that the proportion of acute respiratory infections associated with coronaviruses varied from 8 to 16% during annual respiratory virus season, which generally occurs from October through April in the temperate Northern Hemisphere.[5]

The incidence of symptomatic infection is highest in children below age 5 years for all seasonal coronaviruses except 229E, for which the incidence is relatively consistent across age groups. However, multiple studies indicate that all seasonal coronaviruses can infect individuals of all ages and that reinfection is common.[6]

Seasonal coronaviruses are likely spread via direct contact with respiratory droplets, aerosols, or secretions (Table 334-1). Viral shedding can frequently occur beyond 1 week in both symptomatic and asymptomatic adults and children, with viral detection typically persisting for a longer duration in children under age 5 years. Seasonal coronaviruses have a high attack rate within households; the proportion who become infected after exposure to an infected household member ranges from 7.2% for 229E to 12.6% for NL63. As a result, approximately 25% of all infections are likely acquired from an infected household contact. Children are the most frequently identified index case except for 229E, whereas adults ages 18 to 49 years comprise nearly half of the secondarily infected household contacts. Seasonal coronavirus outbreaks associated with significant morbidity have been described in babies in neonatal intensive care units and in adults in long-term care facilities.

PATHOBIOLOGY

Similar to other human coronaviruses, seasonal coronaviruses are thought to have a zoonotic origin (see Table 334-1)[7] and to attach to human cells via the receptor binding domain of the coronavirus spike protein. NL63 binds to angiotensin converting enzyme 2 (ACE-2), the same receptor as SARS-CoV and SARS-CoV-2. By comparison, 229E binds aminopeptidase N, whereas OC43 and HKU-1 bind 9-O-acetylated sialic acid. Although both ACE-2

ABSTRACT

All seven coronaviruses that are known to infect humans likely originated from animal reservoirs. Four of these human coronaviruses (HCoV-229E, HCoV-NL63, HCoV-OC43, and HCoV-HKU1) are frequent causes of relatively mild respiratory tract infections and rarely cause severe disease. In recent decades, however, three other coronaviruses have emerged to cause widespread severe disease in humans: SARS-CoV, MERS-CoV, and SARS-CoV-2 (the cause of the COVID-19 pandemic; Chapters 335 to 337). SARS-CoV was transmitted after the onset of symptoms and was successfully eliminated by a combination of public health control measures. In contrast, MERS-CoV infections continue to occur following close contact with infected persons or dromedary camels, primarily in or near the Arabian Peninsula. Infection with any of the known human coronaviruses can be confirmed using nucleic acid amplification tests, with multiplex tests increasingly available. Treatment for all non–SARS-CoV-2 human coronaviruses is supportive, although antiviral therapies and vaccines for MERS-CoV are currently being developed and evaluated.

TABLE 334-1 ORIGINS, TRANSMISSION, CLINICAL FEATURES, AND INFECTIOUSNESS OF HUMAN CORONAVIRUSES IDENTIFIED BEFORE 2019

	HUMAN CORONAVIRUS		
	229E, NL63, OC43, HKU1	**SARS**	**MERS**
Postulated original animal reservoir	Bats (229E, NL63) Rodents (OC43, HKU1)	Bats	Bats
Intermediate host	Dromedary camels (229E) Unknown (NL63) Cattle (OC43) Unknown (HKU1)	Palm civet	Dromedary camels
Estimated date of first human infections	1700 (229E) 1200-1500 (NL63) 1890 (OC43) 1950s (HKU1)	2003	1980s (first case described 2012)
Source of transmission	Human infections, especially community settings	Human infections, especially health care settings (no cases reported since 2004)	Human infections, especially health care settings Contact with dromedary camels
Likely predominant route of transmission	Respiratory droplets or aerosols	Respiratory droplets or aerosols	Respiratory droplets or aerosols
Median incubation period (95% confidence interval)	3.2 days (95% CI, 2.8-3.7 days)	4.0 days (95% CI, 3.6-4.4 days); maximum 14 days	5.2 days (95% CI, 1.9-14.7 days)
Typical presentation	Upper respiratory tract infection; occasionally lower respiratory tract infections, especially if immunocompromised; croup or bronchiolitis in children	Upper respiratory tract infection, progressing to respiratory tract involvement in severe cases with multisystem involvement	Ranges from mild upper respiratory tract infection to lower respiratory tract infection with multisystem involvement
Infectious period	Typically 1-2 weeks, longer if immunocompromised; limited information on shedding of live virus	Symptom onset to 21 days Transmission usually 4-5 days after onset	Usually 1-11 days after onset of symptoms (median 7 days)

MERS = Middle East respiratory syndrome; SARS = severe acute respiratory syndrome.

and aminopeptidase N are present in a range of human tissues, host tropism of human coronaviruses is also determined by the presence of host proteases that cleave the S1 and S2 components of the spike protein, thereby permitting cell fusion and entry of viral RNA.

Seasonal coronaviruses predominantly infect cells of the upper respiratory tract. NL63, OC43, and HKU1 infect ciliary cells, whereas 229E preferentially infects nonciliary cells but can still depress ciliary function. The cytopathic effect of seasonal coronaviruses appears to be generally limited to the upper respiratory tract, although bronchiolitis, pneumonia, and acute lung injury also have been reported. The association of rare severe pulmonary disease with immunocompromise indicates the importance of the host immune response. Outside the respiratory tract, OC43 can infect neurons, and the virus has a mutation that likely enables cleavage by host cells in the nervous system. OC43 infection has been linked to neurologic syndromes including encephalitis.[8]

CLINICAL MANIFESTATIONS

Asymptomatic infections occur frequently. In human challenge studies, 72% of adults infected with 229E develop cold symptoms, with an incubation period of 2 to 5 days (median 3 days). The incubation period for the four seasonal coronaviruses is similar to other human coronaviruses (see Table 334-1) and has been estimated to be 3.2 days. Clinical manifestations of 229E, OC43, NL63, and HKU1 are generally mild and similar to those of other viral causes of the common cold (Chapter 329). Rhinorrhea, sore throat, cough, wheezing, and fever are common presenting symptoms. In a multiyear prospective household study, about 10% of infections in adults and 20% of infections in children were associated with medical consultation, with about 30% of coronavirus detections associated with moderate illness and 10% with relatively severe illness, which was defined as wheezing, dyspnea, or seeking care for the illness. Such infections are more likely in children under age 5 years and in adults age 50 years or older, and are more likely to be caused by 229E virus infection compared with the other three seasonal coronaviruses. Overall, about 5% of all hospitalized adults with acute respiratory illnesses are associated with these coronaviruses in the pre-COVID era.[9] Otitis media, gastroenteritis, an exacerbation of prior asthma, and pneumonia[10] occur more frequently in individuals who are immunocompromised or have underlying medical conditions. Rare neurologic manifestations such as meningoencephalitis and seizures have been noted in children with seasonal coronavirus infections, including fatal encephalitis in immunocompromised infants infected with OC43.

DIAGNOSIS

Given the lack of specific treatment, confirmatory diagnosis of these pathogens is generally of limited clinical utility. However, testing of nasopharyngeal samples with multipathogen respiratory viral panels using polymerase chain reaction (PCR) assays, often to exclude other pathogens such as SARS-CoV-2, is the best method for confirming the diagnosis.

TREATMENT

No specific antiviral treatment is currently recommended for seasonal coronavirus infections. Supportive care or management of complications from infection is occasionally warranted. Remdesivir, an antiviral active against SARS-CoV-2, has in vitro activity against 229E, and other compounds examined for activity against SARS-CoV-2 potentially show promise against seasonal coronaviruses, but none have been evaluated in rigorous clinical trials.

PREVENTION

During months of active circulation, transmission can be prevented by nonpharmaceutical precautions such as washing hands regularly and avoiding close contact with a person who has an upper respiratory tract infection. A decline in infections from seasonal coronaviruses during the COVID-19 pandemic showed that school closures or other precautions related to the pandemic likely prevented transmission of seasonal coronaviruses as well as SARS-CoV-2.[11] In health care settings, general infection control practices should be maintained to prevent transmission via respiratory droplets, especially for patients at extremes of age or with known immunocompromised status. COVID-19 vaccines elicit cross-reactive immune responses to seasonal coronaviruses, although it is not yet known if true cross-protection results. Prior infection with a seasonal coronavirus appears to provide limited cross-protection against SARS-CoV-2 infection.

PROGNOSIS

Although most cases are mild, severe illness has been documented in some patients, particularly patients who are immunocompromised, have underlying comorbid conditions, or are at the extremes of age.

MIDDLE EAST RESPIRATORY SYNDROME AND SEVERE ACUTE RESPIRATORY SYNDROME

EPIDEMIOLOGY

Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) is a viral respiratory illness caused by a coronavirus called SARS-associated coronavirus (SARS-CoV or SARS-CoV-1). Following reports of an atypical pneumonia in Guangdong, China, in November 2002, SARS-CoV spread to more than two dozen countries in North America, South America, Europe, and Asia, where it resulted in a sizeable international outbreak.[12] Before the SARS global outbreak of 2003 was contained, 8098 reported infections and 774 reported deaths occurred. Since mid-2004, no cases of SARS have been reported.[13]

The median incubation period for SARS was estimated to be 4 days, although incubation periods of up to 14 days were reported (see Table 334-1). SARS was spread primarily by close person-to-person contact, via respiratory droplets or aerosol, or less commonly via fomites. Likely transmission from fecal contamination was also reported.

Transmission of SARS-CoV typically occurred 4 or 5 days after onset of symptoms and was driven predominantly by more severely ill, hospitalized patients. Viral load was highest around day 10 of illness, with no virus isolated beyond 21 days. Asymptomatic and mild infections were rare, and no transmission was reported from asymptomatic individuals or from symptomatic cases before the onset of symptoms.

Middle East Respiratory Syndrome

Middle East respiratory syndrome (MERS), the illness caused by MERS-CoV-2 infection, was first reported in Saudi Arabia in September 2012. Most infected individuals with MERS have lived in the Arabian Peninsula or recently traveled from the Arabian Peninsula before they became ill, but some individuals have contracted MERS after having close contact with an infected person who had recently traveled from the Arabian Peninsula. At least 27 countries have reported cases since 2012, leading to more than 900 known deaths owing to the infection and related complications.

Transmission of MERS-CoV leading to human illness likely originates from upper respiratory tract infections among camels, specifically dromedaries (*Camelus dromedarius*).[14] Direct contact with dromedaries is a risk factor for primary human infection with MERS-CoV (see Table 334-1).

More than 80% of MERS-CoV infections are estimated to result from human-to-human transmission through close contact, most likely via respiratory droplets. Human-to-human transmission frequently occurs in health care settings. Transmission can also occur in household settings, but epidemiologic studies have not found sustained community transmission of MERS-CoV.

The majority of human-to-human transmission seems to originate from symptomatic case patients. Evidence for transmission from asymptomatic individuals is limited, but the importance of asymptomatic infections might be underappreciated, because a substantial proportion of MERS cases do not report having a known risk factor (i.e., contact with another case or a dromedary).[15]

The median incubation period for MERS is approximately 5 days (95% confidence interval, 1.9 to 14.7 days). Duration of MERS-CoV shedding in the respiratory tract is typically longer in severely ill patients compared with mildly ill patients. Shedding of cultivable virus has been detected for up to 25 days after the onset of symptoms.

PATHOBIOLOGY

After infection of epithelial cells in the upper respiratory tract, SARS-CoV and MERS-CoV can infect pneumocytes and cells in other organ systems. Tissue tropism is determined by the host receptor that binds to the coronavirus spike protein and by other factors such as host cell proteases.

Like SARS-CoV-2, the SARS-CoV spike protein binds to the ACE-2 receptor, which is abundant in epithelial, endothelial, and smooth muscle cells. Autopsy investigations of patients with SARS have noted SARS-CoV in pneumocytes, pulmonary infiltrates, the reticuloendothelial system, kidneys, gastrointestinal tract, and brain.

The MERS spike protein binds to the dipeptidyl peptidase 4 (DPP4) receptor, which is present in a variety of cell types, including epithelial cells, pneumocytes, endothelial cells, neurons, and T-cells. Autopsy after fatal MERS infection has indicated necrotizing pneumonia with diffuse alveolar damage, acute kidney injury, and other organ involvement, including hepatitis and myositis.

Pathologic damage from SARS and MERS coronavirus infections is likely caused by a combination of cytopathic effects and the host immune response. The importance of immunopathology is indicated by the typical timing of severe illness after peak viral load, and by the association of a delayed type I interferon response with severe outcomes. Conversely, an early type I interferon response and neutralizing antibody appear to be protective.

CLINICAL MANIFESTATIONS

Severe Acute Respiratory Syndrome

The clinical manifestations of SARS-CoV infection range from mild illness to severe and rapidly progressive disease. SARS-CoV infection typically begins with a fever that is sometimes associated with other nonspecific symptoms such as chills, headache, or myalgias. These nonspecific systemic symptoms progress 2 to 7 days later to pulmonary disease and a clinical syndrome indistinguishable from other causes of community-acquired pneumonia (Chapter 85). Respiratory complaints include a nonproductive cough and dyspnea, but typically do not include upper respiratory tract symptoms such as rhinorrhea and sore throat. Almost all patients with laboratory evidence of SARS-CoV infection develop radiographic evidence of pneumonia, and most (70 to 90%) develop lymphopenia. In 10 to 20% of cases, patients progress to develop acute respiratory distress syndrome (ARDS; Chapter 90) and ultimately require mechanical ventilation. Diarrhea, which is seen in approximately 10 to 20% of patients, typically develops later in the illness.

Middle East Respiratory Syndrome

Clinical features of MERS-CoV infection range from asymptomatic or mild disease (with low-grade fever, runny nose, sore throat, or muscle aches) to severe disease. In patients confirmed to have MERS-CoV infection, the disease may progress to severe respiratory illness with symptoms such as fever, cough, and shortness of breath; some patients also have diarrhea and nausea/vomiting. Chest radiographs and/or computed tomographic (CT) scans are typically normal in patients with mild illness, but severe illness can include ARDS with variable multiorgan involvement. Laboratory abnormalities commonly include leukopenia and lymphopenia; some patients also develop thrombocytopenia, anemia, and elevated aminotransferase levels. Severe MERS can progress rapidly to respiratory failure, acute kidney injury, and death.

DIAGNOSIS

Severe Acute Respiratory Syndrome

The assays most often used to diagnose SARS-CoV infection were PCR assays for viral RNA and serologic testing for virus-specific antibodies. Given the lack of any known SARS cases in the world since 2004, any decision to test for SARS should be made in conjunction with public health authorities.

Middle East Respiratory Syndrome

Individuals may be suspected of having MERS if they have both a clinical syndrome consistent with MERS (e.g., fever and respiratory symptoms) and an epidemiologic link to the Arabian Peninsula, a history of travel to the Arabian Peninsula, close contact with an ill traveler from the Arabian Peninsula, or close contact with a confirmed case of MERS.[16] Because the clinical features of MERS often do not differ from those of other acute febrile respiratory illnesses, other causes of community-acquired pneumonia should be considered with appropriate testing and/or treatment (Chapter 85).

PCR testing of respiratory secretions, done in consultation with local public health authorities, is the mainstay for diagnosis. Samples from the lower respiratory tract (collected within 7 days after the onset of symptoms) have the highest sensitivity among seriously ill patients, but multiple specimens (e.g., sputum, nasopharyngeal swabs, oropharyngeal swabs, bronchoalveolar lavage and tracheal aspirates) should be analyzed to optimize the likelihood of obtaining a positive test.

TREATMENT

No specific antiviral treatments are currently recommended for SARS or MERS. Lopinavir can limit the replication of SARS-CoV and MERS-CoV in vitro, and treatment of SARS with the combination of lopinavir plus ritonavir resulted in lower mortality compared with an untreated historical control group who were treated with ribavirin alone. Interferon is of uncertain effectiveness.

For MERS, one randomized trial found that up to 14 days of treatment with interferon beta-1b (0.25 mg on alternate days) plus lopinavir-ritonavir (400 mg

lopinavir and 100 mg ritonavir every 12hours) significantly lowered 90-day all-cause mortality from 44 to 28% compared with placebo, with the greatest effect when treatment is started during the 7 days after the onset of symptoms.[A1] Remdesivir inhibits SARS-CoV and MERS-CoV replication in vitro and in animal models. Neither monoclonal antibodies nor convalescent plasma have been tested in rigorous clinical trials.

Seriously ill patients require progressively more intense supportive care, as is recommended for pneumonia (Chapter 85) and acute respiratory failure (Chapter 90). Glucocorticoids are not recommended for MERS-CoV infections.

PREVENTION

During 2003, SARS transmission levels were dependent on super-spreader events that originated from symptomatic infections. The transmission of SARS was effectively eliminated within a few months by a combination of case detection, contact tracing, isolation, quarantine, infection control practices during health care, and temporary travel restrictions.

Prevention of MERS requires ongoing strategies because dromedaries in the Arabian Peninsula remain an important source of primary human infections. Human-to-human transmission also occurs, but human-to-human transmission chains are not sustained. Infection with MERS-CoV can elicit persistent humoral and cellular immunity.[17] Nevertheless, early identification and triage is critical to prevent onward transmission. Consistent implementation of infection control protocols can prevent health care–associated outbreaks. Handwashing and other precautions are recommended when in contact with dromedaries to prevent zoonotic transmission.

Candidate vaccines for dromedaries have been evaluated. Early studies of human vaccines against MERS are also underway, using different approaches to elicit immune responses against the spike protein.

PROGNOSIS

For patients with SARS, the overall case fatality rate was estimated to be 15%, with higher mortality among older age groups. The case fatality rate for MERS is between 20 and 40%, although the number of asymptomatic and/or mild cases may be underreported. Most people who die of MERS are older and/or have preexisting medical conditions, such as diabetes, hypertension, cardiac disease, obesity, chronic respiratory disease, end-stage renal disease, cancer, or immunosuppressive therapy. Concomitant infections, a low albumin concentration, admission to an intensive care unit, and the need for mechanical ventilation are predictors of death.

Similar to what has been observed following COVID-19 (Chapter 337), some survivors of SARS and MERS have significant long-term clinical problems, including impaired lung function and decreased exercise capacity. The prevalence of psychological sequelae, such as post-traumatic stress disorder, depression, and anxiety, is 30% or higher after more than 6 months.[18]

335 COVID-19: VIROLOGY AND PATHOLOGY

VINCENT RACANIELLO

In December 2019, a cluster of patients with pneumonia of unknown etiology were identified in Wuhan, a city of 11 million residents in South Central China.[1] RNA extracted from bronchoalveolar fluid provided the complete genome of a novel betacoronavirus named SARS-CoV-2 (for severe acute respiratory syndrome coronavirus-2). The disease caused by this virus is called COVID-19 (for COronaVirus Infectious Disease).

SARS-COV-2: THE VIRUS AND THE GENOME

SARS-CoV-2 is classified within the Coronaviridae, a diverse family of viruses with (+) strand RNA genomes (Table 335-1). Coronaviruses, which infect not only humans but also other mammalian and avian species, may cause respiratory or enteric diseases. SARS-CoV-2 is the seventh coronavirus known to infect humans. Four of these human coronaviruses (HCoV-229E, HCoV-OC43, HCoV-NL63, HCoV-HKU1) cause mainly mild upper respiratory tract infections (Chapter 334). By comparison, severe acute respiratory syndrome coronavirus (SARS-CoV), which was identified in 2002, precipitated an epidemic that infected about 8000 humans before its circulation ceased. Middle East Respiratory Syndrome coronavirus (MERS-CoV) was first identified in 2012 and continues to infect humans, although chains of infection are very short, and only about 2500 confirmed cases have been reported.

Coronaviruses, which have the appearance of a solar corona on electron microscopy (Fig. 335-1), are enveloped, roughly spherical, and pleomorphic, with particle sizes ranging from approximately 118 to 136 nm in diameter. Embedded in the viral membrane are the spike (S), membrane (M), and envelope proteins (Fig. 335-2). The transmembrane S protein forms trimers that bind to host cell receptors and induce fusion of viral and cell membranes. The M protein monomer, which provides shape to the viral particles, is embedded in the viral membrane by three transmembrane domains. The E protein is a small (8- to 12 kDa) protein that is essential

Most people who die of MERS are older and/or have preexisting medical conditions, such as diabetes, hypertension, cardiac disease, obesity, chronic respiratory disease, end-stage renal disease, cancer, or immunosuppressive therapy. Concomitant infections, a low albumin concentration, admission to an intensive care unit, and the need for mechanical ventilation are predictors of death.

Similar to what has been observed following COVID-19 (Chapter 337), some survivors of SARS and MERS have significant long-term clinical problems, including impaired lung function and decreased exercise capacity. The prevalence of psychological sequelae, such as post-traumatic stress disorder, depression, and anxiety, is 30% or higher after more than 6 months.[18]

335 COVID-19: VIROLOGY AND PATHOLOGY

VINCENT RACANIELLO

In December 2019, a cluster of patients with pneumonia of unknown etiology were identified in Wuhan, a city of 11 million residents in South Central China.[1] RNA extracted from bronchoalveolar fluid provided the complete genome of a novel betacoronavirus named SARS-CoV-2 (for severe acute respiratory syndrome coronavirus-2). The disease caused by this virus is called COVID-19 (for COronaVirus Infectious Disease).

SARS-COV-2: THE VIRUS AND THE GENOME

SARS-CoV-2 is classified within the Coronaviridae, a diverse family of viruses with (+) strand RNA genomes (Table 335-1). Coronaviruses, which infect not only humans but also other mammalian and avian species, may cause respiratory or enteric diseases. SARS-CoV-2 is the seventh coronavirus known to infect humans. Four of these human coronaviruses (HCoV-229E, HCoV-OC43, HCoV-NL63, HCoV-HKU1) cause mainly mild upper respiratory tract infections (Chapter 334). By comparison, severe acute respiratory syndrome coronavirus (SARS-CoV), which was identified in 2002, precipitated an epidemic that infected about 8000 humans before its circulation ceased. Middle East Respiratory Syndrome coronavirus (MERS-CoV) was first identified in 2012 and continues to infect humans, although chains of infection are very short, and only about 2500 confirmed cases have been reported.

Coronaviruses, which have the appearance of a solar corona on electron microscopy (Fig. 335-1), are enveloped, roughly spherical, and pleomorphic, with particle sizes ranging from approximately 118 to 136 nm in diameter. Embedded in the viral membrane are the spike (S), membrane (M), and envelope proteins (Fig. 335-2). The transmembrane S protein forms trimers that bind to host cell receptors and induce fusion of viral and cell membranes. The M protein monomer, which provides shape to the viral particles, is embedded in the viral membrane by three transmembrane domains. The E protein is a small (8- to 12 kDa) protein that is essential

ABSTRACT

A novel betacoronavirus named SARS-CoV-2 emerged in South Central China in December 2019 after a spillover from wild animals to humans at the Wuhan Huanan Seafood market. The virus particle is enveloped and harbors an RNA genome of nearly 30,000 bases in length. SARS-CoV-2 initiates infection of cells when the S protein binds to the cell receptor ACE2. In cells of the respiratory tract, the plasma membrane protease TMPRSS2 cleaves S into its S1 and S2 subunits. Upon the attachment of the receptor-binding domain to ACE2, the conformation of S2 changes to thrust the fusion peptide into the cell membrane. Consequently, fusion of viral and cell membranes occurs at the cell surface. SARS-CoV-2 is transmitted among humans by droplets that are produced by speaking, sneezing, or coughing. Virus-laden droplets are inhaled and lodge in the upper respiratory tract, where the virus attaches to and enters ciliated epithelial cells. After initial reproduction in the upper respiratory tract, virus migrates down the airways, where it may infect alveolar epithelial cells in the lungs. In the lungs, diffuse alveolar injury, exudates, and hyaline membranes are accompanied by endothelial injury with microangiopathy, microthrombosis, and vascular angiogenesis. In some cases, viral reproduction can trigger strong unregulated immune responses (cytokine storm) associated with inflammation-mediated acute lung injury, increases in vascular permeability, thrombosis, disseminated intravascular coagulation, acute respiratory distress syndrome, and generalized organ failure. SARS-CoV-2 infections have been documented in many nonhuman animal hosts, so the virus can never be eradicated.

for infectivity, but its function is enigmatic. The nucleocapsid (N) protein, which is the most abundant protein in the infected cell, is required for replication of the genome, coats the entire viral RNA genome, and interacts with the M protein.

Coronavirus genomes are the longest among RNA viruses, and the SARS-CoV-2 genome is nearly 30,000 bases in length (Fig. 335-3). The virion RNA is capped at the 5′-end and polyadenylated at the 3′-end and harbors 5′- and 3′-untranslated regions. The left two-thirds portion of the viral RNA encodes two overlapping open reading frames that specify proteins involved in mRNA synthesis and genome replication; no other polypeptides are translated from the viral genome RNA. The remainder of the genome, which encodes structural and accessory proteins, is expressed by means of a nested set of subgenomic RNAs.

ORIGIN OF SARS-COV-2

The closest genome to SARS-CoV-2 is a virus called RaTG13, which was obtained from a *Rhinolophus affinis* bat in 2013 in Yunnan province, China.[2] The genome of this bat virus is overall 96.2% identical to that of SARS-CoV-2, a divergence that represents about 20 years of sequence evolution. Consequently, RaTG13 cannot be a direct progenitor of SARS-CoV-2 but is clearly in its evolutionary past.

Various SARS-CoV-2–like viruses have been isolated from bats in China, Thailand, Cambodia, and Japan, but none have a spike protein that can bind angiotensin-converting enzyme 2 (ACE2) and allow entry into human cells.[3] In limestone caves in Northern Laos, however, sampling of bats has revealed the presence of three *Sarbecovirus* genomes (called BANAL-52, BANAL-103, and BANAL-236) with high sequence similarity to SARS-CoV-2 and RaTG13.[4] Of the 17 amino acids that interact with the receptor-binding domain of ACE2, 16 are conserved between SARS-CoV-2 and BANAL-52 or BANAL-103, and 15 of 17 are conserved with BANAL-236. In contrast, only 11 out of 17 receptor-binding domain amino acids are conserved among SARS-CoV-2 and RaTG13. Recombination analysis demonstrates that the SARS-CoV-2 genome is a mosaic of at least five different genomes, including BANAL-52, BANAL-103, and BANAL-236 and the previously recognized RmYN02, RpYN06, and RaTG13, the latter all discovered in China. The implication of these observations is that SARS-CoV-2 likely arose from recombination among viruses circulating in different species of *Rhinolophus* bats in the limestone caves of South China and Southeast Asia.

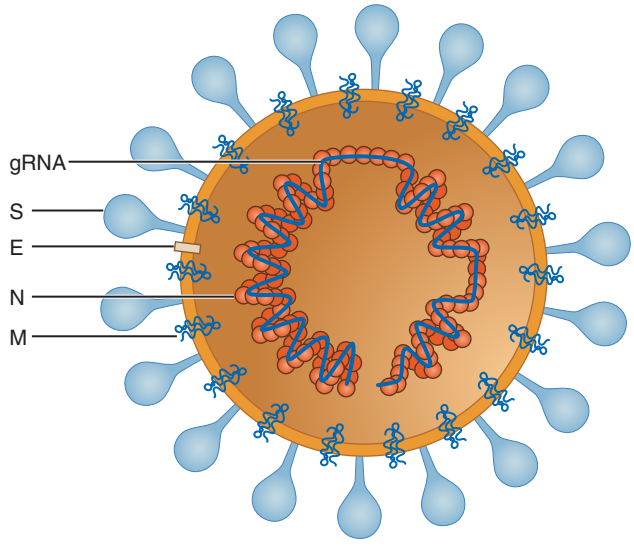

FIGURE 335-2. Schematic drawing of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) viral particle. The viral spike (S), membrane (M) protein, and envelope (E) proteins are shown embedded in the viral membrane. The viral RNA genome is shown as a blue line coated with orange nucleocapsid (N) protein. (Modified from https://www.cell.com/cell/fulltext/S0092-8674(20)30406-2#gr1.)

SARS-CoV-2 INFECTION OF CELLS

SARS-CoV-2 initiates infection of cells when the S protein binds to the cell receptor ACE2. This same cell protein also serves as a receptor for SARS-CoV and HCoV-NL63. The S protein is functionally divided into two parts, S1 and S2, which are separated by a protease cleavage site (Fig. 335-3). A feature of the SARS-CoV-2 S protein is the presence of a polybasic cleavage site (PRRAR) near the S1-S2 boundary (Fig. 335-4). This cleavage site allows processing by furins and enhances infectivity. A furin cleavage site has not been identified in betacoronaviruses but is present in other human coronaviruses such as HCoV-HKU1, HCoV-OC43, and MERS-CoV. The receptor-binding domain is located in S1, whereas the fusion peptide, which drives fusion of the viral and cell membranes, is located in S2. In cells of the respiratory tract, the plasma membrane protease TMPRSS2 cleaves S into its S1 and S2 subunits. After S has been proteolytically cleaved, the S1 subunit falls away. Upon the attachment of the receptor-binding domain to ACE2, the conformation of S2 changes to thrust the fusion peptide into the cell membrane. Consequently, fusion of viral and cell membranes occurs at the cell surface.

In cells that lack TMPRSS2, fusion does not occur at the plasma membrane but occurs instead from within endosomes, where cleavage of the S protein is carried out by endosomal cathepsins. These proteases are activated by low pH within endosomes, thereby explaining why hydroxychloroquine, which prevents acidification of endosomes, can block SARS-CoV-2 reproduction in kidney cells. However, hydroxychloroquine has no effect on viral reproduction in the respiratory tract because entry in these cells occurs at the plasma membrane.

Once the SARS-CoV-2 genome is released into the cytoplasm, it is engaged by ribosomes, and the ORF1a and ORF1b open reading frames are translated to form two polyproteins (see Fig. 335-3). These polyproteins are co-translationally processed by two virus-encoded proteases, PL^{pro} and M^{pro}, to produce the proteins needed for viral RNA synthesis, including the RNA-dependent RNA polymerase (RdRp). Viral RNA synthesis occurs on and within double-membrane vesicles, which are induced by viral proteins. The viral RNA genome is copied to form a full-length (−) RNA, which can be a template to produce full-length (+) RNA or for mRNA synthesis of the subgenomic RNAs that encode the structural proteins and several accessory proteins, which are thought to modulate viral pathogenesis. This latter process occurs by discontinuous synthesis and leads to the formation of multiple subgenomic mRNAs, each encoding a single polypeptide (see Fig. 335-3). Coronavirus RNA synthesis is

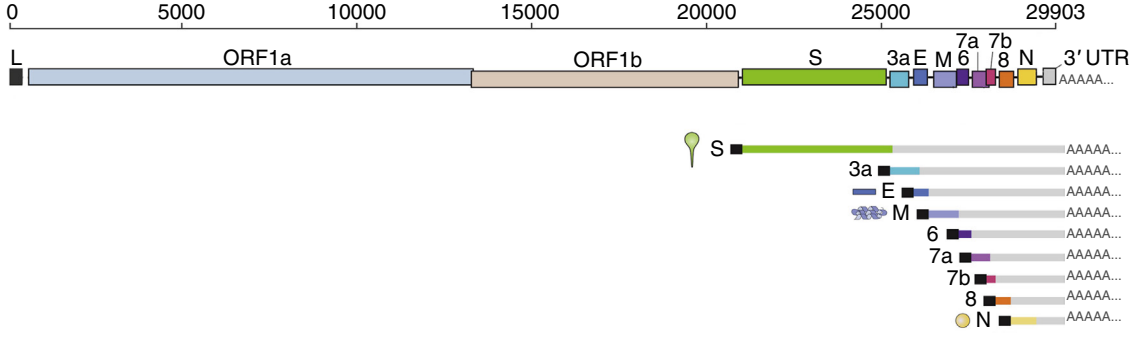

FIGURE 335-3. Open reading frames in the genome of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2). The 29,903 nt (+) strand RNA is translated to produce polyproteins ORF1a and ORF1b, which are further processed by two virus-encoded proteases to form the viral RNA-dependent RNA polymerase and accessory proteins. The remainder of the viral proteins are translated from nine subgenomic mRNAs encoding S, E, M, N, and other accessory proteins. ORF = open reading frame. (Adapted from https://www.cell.com/cell/fulltext/S0092-8674(20)30406-2#gr1.)

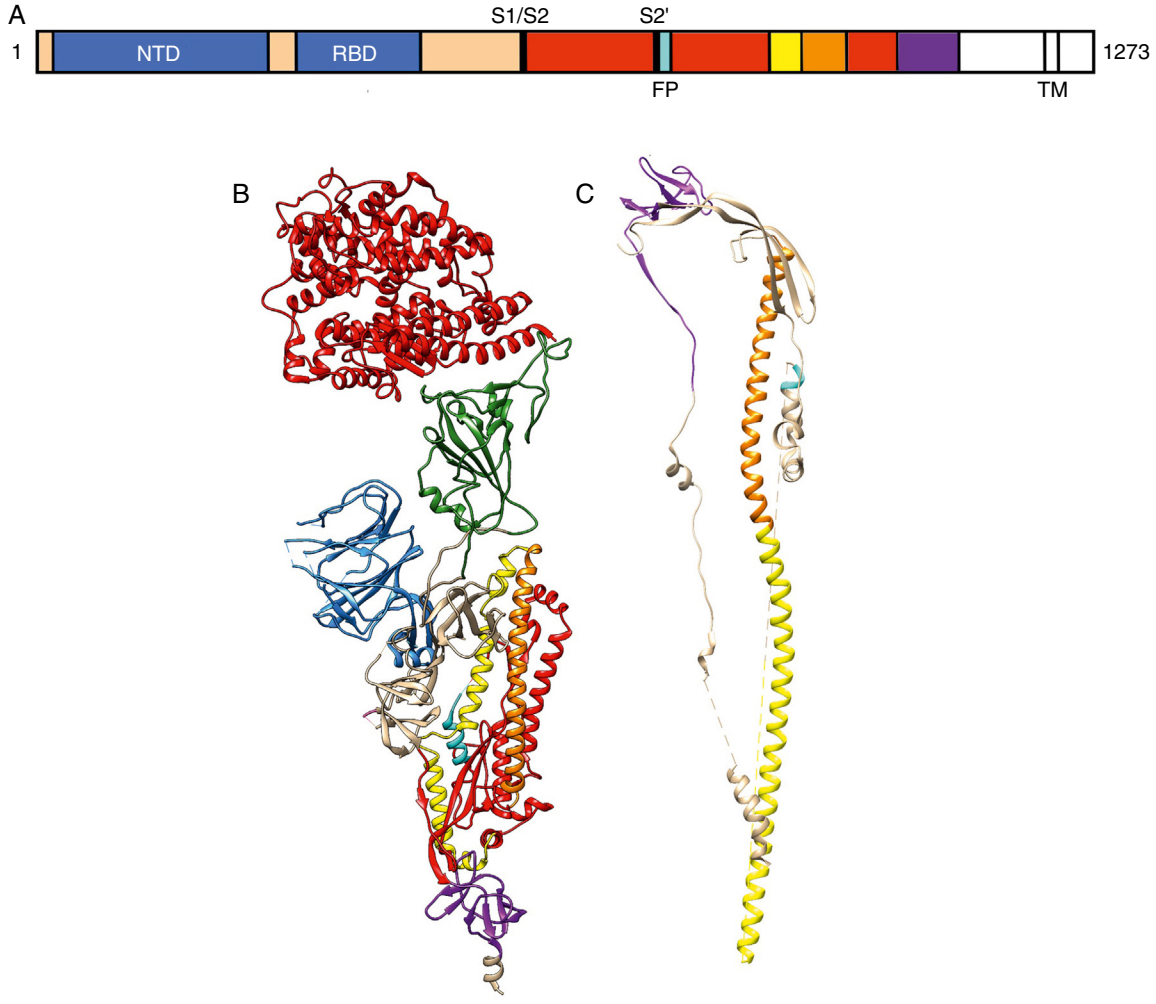

FIGURE 335-4. Functional domains of the severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) spike protein. The box at the top shows a schematic of the 1273-amino-acid-long S protein. The N-terminal domain (NTD), receptor binding domain (RBD), fusion peptide (FP), S1/S2 and S2′ cleavage sites are labeled. Below are structural models of the S protein monomer in a prefusion state bound to the receptor ACE2 (B) and in a postfusion state (C). Domains of the S protein in (B) and (C) are colored according to the domains shown in (A). (From Protein Data Bank files 7KMS and 6XRA.)

unique among RNA viruses because the genome encodes an error-correcting endonuclease, nsp14 (ExoN), whose presence allows the correction of errors made by the RNA-dependent RNA polymerase and may have permitted the evolution of such long RNA genomes.

Two viral enzymes, RNA-dependent RNA polymerase and the M^{pro} protease, are among the many viral proteins that are targets for experimental antiviral compounds. For example, nirmatrelvir (a protease inhibitor) and molnupiravir (which targets the RNA-dependent RNA polymerase) target those enzymes.

Assembly of new infectious virus begins as the M, S, and E proteins are inserted co-translationally into the endoplasmic reticulum. These proteins then move to the site of viral assembly, which is the endoplasmic reticulum–Golgi intermediate compartment. Nucleocapsids formed by the association of the N protein with (+) viral RNA bud into the endoplasmic reticulum–Golgi intermediate compartment, thereby forming viral particles. Viral particles move to the plasma membrane within smooth-walled vesicles and are released from the cell by exocytosis.

COVID-19

SARS-CoV-2 is transmitted among humans by droplets that are produced by speaking, sneezing, or coughing. Although transmission is mainly associated with small infectious droplets, which fall to the ground within 3 to 5 feet, infection may also be spread more rarely by infectious droplet nuclei, which can remain suspended in the air and travel over 100 feet.[5] Fomites have not been demonstrated to play a role in human-to-human transmission.

Virus-laden droplets are inhaled and lodge in the upper respiratory tract, where the virus attaches to and enters ciliated epithelial cells. The incubation period, defined as the time before the onset of symptoms, ranges from 1 to 14 days (average 5 days). Large quantities of viral RNA can be detected in nasopharyngeal secretions, and expulsion of droplets containing newly synthesized virus is responsible for onward transmission. The peak production of virus in the upper respiratory tract occurs at or shortly before the onset of symptoms.[6] These kinetics, together with the observation that approximately 20% of infections are asymptomatic, contribute to widespread community transmission of the virus. This situation contrasts with SARS-CoV, for which viral shedding peaked after the onset of symptoms when over 50% of patients had already been hospitalized.

After initial reproduction in the upper respiratory tract, virus migrates down the airways, where it may infect alveolar epithelial cells in the lungs.[7] During this symptomatic viral phase, viral RNA loads in the upper respiratory tract decline rapidly, and within 7 days they are typically below the levels associated with transmission. In the lungs, diffuse alveolar injury, exudates, and hyaline membranes are accompanied by endothelial injury with microangiopathy, microthrombosis, and vascular angiogenesis. Lymphocytic myocarditis and pericarditis can also occur. These vascular findings generally distinguish SARS-CoV-2 from what is seen in equivalently sick patients with influenza (Chapter 332).

In some cases, viral reproduction can trigger strong unregulated immune responses (cytokine storm) associated with inflammation-mediated acute lung injury, increases in vascular permeability, thrombosis, disseminated intravascular coagulation (Chapter 161), acute respiratory distress syndrome (Chapter 90), and generalized organ failure. Many patients experience anosmia or ageusia, which appear to be consequences of viral reproduction in sustentacular cells of the olfactory mucosa.[8] Although SARS-CoV-2 infection can lead to signs and symptoms in diverse organ systems (e.g.,

TABLE 335-2 VARIANTS OF SEVERE ACUTE RESPIRATORY SYNDROME CORONAVIRUS-2

KEY VARIANTS	FIRST IDENTIFIED	KEY AMINO ACID CHANGES	EFFECT OF VACCINATION	NEUTRALIZATION BY ANTIBODIES
Alpha (B.1.1.7)	UK September 2020	N501Y, D614G, P681H	Two mRNA vaccine doses protect against severe disease and death	No change
Beta (B.1.351)	South Africa, May 2020	K417N, E484K, N501Y, D614G, A701V	Two mRNA vaccine doses protect against severe disease and death	Reduced in vitro susceptibility to bamlanivimab and etesevimab. Combination of casirivimab and imdevimab retains activity against the variant, as does sotrovimab.
Delta (B.1.617.2)	India, October 2020	L452R, T478K, D614G, P681R	Two mRNA vaccine doses protect against severe disease and death	Six-fold less sensitive to serum neutralizing antibodies from recovered individuals, and eight-fold less sensitive to vaccine-induced antibodies. Resistant to neutralization with bamlanivimab.
Omicron (BA.1, BA.2, BA.4, BA.5)	South Africa, November 2021		Three mRNA vaccine doses protect against severe disease and death	Bebtelovimab and tixagevimab/cilgavimab retain activity against all circulating omicron variants.

mRNA = messenger ribonucleic acid.
Monoclonal antibody data from https://www.covid19treatmentguidelines.nih.gov/tables/variants-and-susceptibility-to-mabs/ and https://www.biorxiv.org/content/10.1101/2022.05.03.490409v1.

central nervous system, circulatory system, kidneys, and gastrointestinal system), there is no convincing evidence that these symptoms are a consequence of viral reproduction. Rather, the cytokine imbalance and hypoxia associated with infection appear to be responsible for pathogenesis outside of the respiratory tract.

THE IMMUNE RESPONSE

The clinical course of COVID-19 ranges from silent infection (40% of cases) to acute respiratory distress syndrome (about 3% of cases) and death (about 1% of cases; Chapter 336). Severe COVID-19 is characterized by persistent lung infection and inflammatory cytokine production. The strongest epidemiologic predictor of death is age (Chapter 337), with risk doubling every 5 years.[9] Type I interferon (IFN) is essential for protective immunity, and an early interferon response likely occurs in the majority of patients who rapidly clear infection.[10] Patients who have inborn errors in the genes that comprise the interferon system develop lethal disease. In addition, multiple lines of evidence indicate that autoantibodies against type I interferon are strong determinants of COVID-19 death.[11] Another cause of severe disease is SARS-CoV-2 replication in lung-resident macrophages.[12] In response to infection, these cells activate inflammasomes, release the proinflammatory cytokines IL-1 and IL-18, and undergo pyroptosis, which contributes to the hyperinflammatory state of the lung[13]

VARIANTS OF CONCERN

SARS-CoV-2 variants of concern are more fit than variants that they displace in the population.[14] Viral fitness can be influenced by many factors, including the intrinsic transmissibility of the virus, its resistance to antibodies, its speed of replication, the yield of infectious virus from individual cells, and its stability in aerosols. Understanding which of these properties is responsible for the emergence of variants of concern in a population cannot be determined by epidemiologic observations, but studies in cell culture and in animal models may provide some information on what makes a particular variant more fit than others. An important issue is whether new variants of concern can be controlled by preexisting vaccines or monoclonal antibodies.

Early in 2020, a SARS-CoV-2 variant with a single amino acid change from aspartic acid to glycine (D614) at position 614 of the S protein of SARS-CoV-2 emerged and eventually was detected in isolates from all parts of the world. Laboratory and epidemiological data suggested that this new variant was inherently more transmissible than the ancestral isolate, but it is not possible to exclude a human founder effect (i.e., that the virus was simply in the right place at the right time).[15]

Later in 2020, other SARS-CoV-2 variants emerged in different locations around the world and often became the dominant local virus (Table 335-2). For example, the B.1.1.7 (alpha) variant was first observed in the United Kingdom in September 2020 and quickly became the dominant variant. It was subsequently displaced by the B.1.617.2 (delta) variant that had first been detected in India. These and multiple other variants have amino acid changes in the S protein as well as in other viral proteins. Some of the S protein changes impact antibody-mediated neutralization and receptor binding. However, displacement of one variant by another is a consequence of alterations within other viral proteins as well as the S protein.[16]

More recently, the omicron variant became the dominant cause of clinical infection worldwide. This variant of concern was unusual because its genome had more mutations than any other variant. Many of these mutations are in the spike protein gene and lead to 30 amino acid changes, three deletions, and one insertion. These changes account for the increased fitness of this variant and its ability to displace the delta variant. Amino acid changes in the spike protein also result in reduced sensitivity to neutralizing antibodies. Consequently, omicron is able to evade humoral immunity, a property that likely in part accounts for its increased fitness.[17] Whether other changes in omicron proteins, such as in the furin cleavage site, play a role in its increased fitness remains to be determined. Initial reports from South Africa, where omicron was first detected, suggested that this variant was less lethal than the delta variant.[18] However, it is now recognized that although omicron infection may be mild in immune individuals, it is just as lethal as any other SARS-CoV-2 in unvaccinated or immunocompromised patients.[19] Omicron has subsequently further evolved to other subvariants, with BA.4 and then BA.5 displacing BA.1 due to greater fitness and decreased sensitivity to neutralization by antibodies.

Two doses of COVID-19 vaccines provided strong protection against severe disease and death after infection with the ancestral SARS-CoV-2 and all variants of concern until omicron emerged, after which rates of hospitalization and death began to rise. A third vaccine dose was found to broaden the antibody response to omicron and provide stronger protection against severe disease and death (Chapter 337).[20] However, certain individuals, such as the elderly and individuals with other diseases, continue to be susceptible to severe disease and death after infection. Whether vaccine booster doses comprising BA.4 and BA.5 will enhance protection against severe disease and death after levels of antibodies and T cells have returned to homeostatic levels remains uncertain.

SPILL-BACK INFECTIONS OF WILDLIFE

SARS-CoV-2 infections have been documented in many nonhuman hosts, including dogs, cats, deer, zoo animals (tigers, lions, gorillas), and farmed mink.[21] Such infections are of concern because the animals can become reservoirs of the virus, thereby leading to new infections of humans. The transmission cycle of human-animal-human has been documented among workers on mink farms, but culling of mink has successfully limited infection in this farmed species. However, wild white-tailed deer in the United States have been found to be extensively infected with asymptomatic SARS-CoV-2, thereby establishing this species as the first wild animal reservoir of the virus.[22]

It is likely that other wild animals, such as mice,[23] also can be infected with SARS-CoV-2. Since mice represent 40% of all mammals and bats represent 20%, a vast reservoir of SARS-CoV-2 may be maintained in the wild, and such reservoirs in wildlife would mean that the virus could never be eradicated.

336 COVID-19: EPIDEMIOLOGY, CLINICAL MANIFESTATIONS, DIAGNOSIS, COMMUNITY PREVENTION, AND PROGNOSIS

CARLOS DEL RIO, MONICA GANDHI, AND MYRON S. COHEN

EPIDEMIOLOGY

On December 31, 2019, the World Health Organization (WHO) was informed of a cluster of cases of pneumonia of unknown cause in Wuhan City, Hubei Province, China. On January 9, 2020, a novel coronavirus (named severe acute respiratory syndrome coronavirus-2 [SARS-CoV-2]) was identified in samples obtained from these patients,[1] whose disease is now called coronavirus 2019 (COVID-19). Although the precise source of the COVID-19 pandemic is uncertain, data suggest recombination from several related species in bats in South China (Chapter 335). SARS-CoV-2 likely jumped from a bat to an unknown animal, possibly animals being sold at wet markets to humans in Wuhan, China.[2]

Despite aggressive mitigation strategies, the infection rapidly spread and, on March 11, 2020, the World Health Organization (WHO) declared COVID-19 a global pandemic. Cases have occurred in every country.

As of March 2023, the 1.1 million COVID-19 deaths in the United States represented the second highest number of deaths per capita in the world, trailing only Brazil. Total mortality rates in the United States during the COVID epidemic have been about 20% above expected, with excess deaths higher among non-Hispanic Blacks than among other ethnic groups.[3] Overall, about one-third of the increase in all-cause U.S. deaths during the pandemic have been attributable to increases in non-COVID-19 deaths, from causes such as cardiovascular disease, cancer, Alzheimer disease, and diabetes.

The reported number of cases underestimates the overall burden of COVID-19. Seroprevalence surveys suggest that infections exceed the number of reported cases by approximately 10-fold or more.[4] By March 2023, over 6.9 million deaths worldwide were reported from COVID-19, but COVID-19 deaths are likely underreported in some countries. Moreover, up to 12 million excess deaths occurred worldwide related to other medical problems (e.g., cardiovascular disease, cancer, strokes, and other infectious diseases) not adequately treated during the pandemic as well as from other indirect consequences of the pandemic. Worldwide, these 18 million excess deaths represented about a 15% increase in global deaths.[5]

SARS-CoV-2 does not have features of an eradicable virus, because of the presence of animal reservoirs, because of its transmission from asymptomatic or presymptomatic individuals, and because its symptoms resemble those of other respiratory pathogens. The infection therefore is expected to become endemic, thereby leading to an ongoing need for vaccination and therapeutics.

The United States has the highest absolute number of documented COVID-19 deaths of any country worldwide[6] for multiple reasons, including a relatively low rate of use of available vaccines compared with other countries of similar economic status.[7] Moreover, COVID-19 has disproportionately affected racial and ethnic minority groups in the United States, with Black, Hispanic, and Native American individuals comprising a disproportionately high number of infections and deaths. As in other countries, indigenous populations (American Indian and Alaska Native) have the highest number of per capita COVID deaths in the United States. The factors that explain these disparities include more comorbid conditions, distrust of the medical system, and socioeconomic determinants of health, such as poverty, education, housing inequalities, use of public transportation, types of employment, and access to health care (Chapter 4).[8]

Transmission

SARS-CoV-2 is primarily transmitted directly from person to person through respiratory particles (droplet and, on occasion, aerosol). Transmission principally occurs when respiratory particles containing virus are released when the infected person coughs, sneezes, or talks in close contact (within approximately 6 feet or 2 meters) with an uninfected person. SARS-CoV-2 also can be airborne in enclosed, poorly ventilated spaces.[9] By comparison, COVID-19 acquisition through contact with contaminated surfaces is not thought now to be a major route of infection.[10,11] The virus is shed in stool, but the role of fecal-oral transmission is minimal even though surveillance of wastewater can track the prevalence of COVID.

The risk of transmission is higher among household contacts (above 50%) than among work or social contacts (about 1.3%). For all contacts, prolonged (>30-minute) conversations or closer contacts (e.g., sharing a bedroom or vehicle) markedly increase transmission. Asymptomatic transmission is thought to account for about 20% of all transmissions. Transmission outdoors is much less common due to ventilation. For example, a study in Wuhan, China, showed that just 1 of over 7000 infections was linked to outdoor transmission. Indeed, ventilation has emerged as one of the most important nonpharmaceutical mitigation strategies for COVID-19. Finally, global rates of human infection are somewhat lower when the maximum ambient temperature is above 52° F and when the ultraviolet light index is higher.

It is also possible for humans to transmit SARS-CoV-2 to other mammals, and infection has been documented in about 30 species of animals, including dogs, cats, gorillas, farmed mink, ferrets, hamsters, rabbits, otters, mice, lions, tigers, deer, and other mammals (Chapter 335). However, the risk these infected animals pose to humans is still being investigated.

After exposure, the incubation period for COVID-19 ranges from 2 to 14 days, with about 98% of cases having the onset of symptoms by day 12, and a relatively constant median of 5 days among persons without prior immunity or vaccination.[12] Viral shedding appears to begin about 2 to 3 days before the onset of symptoms, to be greatest in the first week of infection, to be uncommon more than 5 days after the onset of symptoms, and to be very unusual by 10 days after the onset of symptoms in mild-to-moderate disease, 15 days in severely ill or immunocompromised patients, or 2 days after clinical resolution.[13] Vaccination reduces the time of infectivity after a subsequent breakthrough infection, with implications for shortening the period of isolation when vaccinated individuals become infected.[14]

As SARS-CoV-2 has evolved, variants have arisen (Chapter 335). Most changes have little to no impact, but some mutations can change transmissibility, the severity of disease, the performance of diagnostic tests, the efficacy of therapeutics such as monoclonal antibodies, or the effectiveness of public health and social mitigation measures. If a variant demonstrates increased transmissibility, increased virulence, or immune evasion, it is classified as a "variant of concern." The alpha (B.1.1.7), beta (B.1.351), gamma (P.1), delta (B.1.617.2), and omicron (B.1.1.529) variants have been designated as variants of concern, and omicron has a number of subvariants (BA.1, BA.2 [including its offshoot BA.2.12.1], BA.3, BA.4, and BA.5). For example, the delta variant was more transmissible than the alpha variant but equally virulent.[15] The omicron variant is more transmissible than delta but less virulent.[16]

CLINICAL MANIFESTATIONS

Prior to the availability of vaccination, patients with SARS-CoV-2 infection had a wide range of clinical symptoms, from asymptomatic infection to critical illness with respiratory failure and multiorgan dysfunction. As many as 40% of infected patients may be asymptomatic,[17] and the proportion of asymptomatic infections appears to have increased since the advent of vaccines. Importantly, some individuals who are asymptomatic at the time of SARS-CoV-2 detection can subsequently develop symptoms, in which case they should be reclassified as presymptomatic. Persons with asymptomatic and presymptomatic infections are contagious, although not to the extent as those with symptomatic disease.[18] Peak transmission potential is likely to be at the onset of symptoms.

Fever, cough, anosmia, and ageusia are the most common symptoms of COVID-19 (Table 336-1).[19] Other common symptoms include fatigue, myalgias, sore throat, headache, dry cough, nasal congestion, and shortness of breath, with sputum production being rare in the early stages. Some patients may also present with nausea, vomiting, and diarrhea. With omicron variants, lower respiratory tract symptoms have become less common and gastrointestinal symptoms somewhat more common.[20]

Patients who develop symptoms are classified into four categories based on the severity of illness (Fig. 336-1): mild, moderate, severe, and

ABSTRACT

The COVID-19 pandemic that began in Wuhan, China, in December 2019, spread globally to cause an unprecedented number of infections and deaths. SARS-CoV-2, the virus that causes COVID-19, is primarily transmitted directly from person to person through respiratory particles. As SARS-CoV-2 variants have emerged, the transmissibility, clinical severity, and response to therapeutic agents, such as monoclonal antibodies, have been impacted. Prior to the availability of vaccination, patients with SARS-CoV-2 infection had a wide variety of clinical symptoms ranging from asymptomatic infection to respiratory failure with multiorgan dysfunction. The variety, magnitude, duration of symptoms, as well as the prognosis after infection are affected by age, comorbid conditions, prior infection, and vaccination status. The diagnosis of SARS-CoV-2 infection is made by the detection of viral elements by either nucleic acid amplification test or an antigen detection test. Most patients who have had COVID-19 recover completely, but some experience prolonged symptoms or develop long-term effects, a condition known as long-COVID or post-acute sequelae of SARS-CoV-2 (PASC). Prevention is best achieved by both vaccination and nonpharmacologic interventions, such as physical distancing, well-fitted masks, and ventilation.

prevention

critical. Among unvaccinated adults, approximately 40% have asymptomatic infection or a mild illness, defined by the presence of symptoms but the absence of hypoxia (oxygen saturation >94%) or pneumonia; 40% have moderate illness, defined by the absence of hypoxia but with evidence of lower respiratory disease based on clinical or imaging findings; 15% have severe illness, based on clinical or radiographic criteria; and 5% have critical illness, defined by the presence of respiratory failure, shock, and/or multiorgan dysfunction.

The variety, magnitude, and duration of symptoms are affected by age, comorbid conditions, prior infection, and vaccination status. Age is the most significant risk factor for progressing to severe illness, with patients over age 65 years having the highest risk. Important comorbid conditions that are more common with aging and that predispose one to severe disease and mortality include diabetes, obesity, cardiovascular disease, renal disease, chronic lung disease, and sickle cell disease. Patients who are transplant recipients, have cancer or HIV infection, or are receiving immunosuppressive therapy have defects in host defense that increase the risk of severe COVID-19. In addition, pregnant women are at increased risk for progression of infection and adverse fetal outcomes. Being unvaccinated is also a significant risk factor for severe illness (Chapter 337),[21] so at-risk groups should be prioritized for booster vaccinations, monitored closely, and prioritized for early treatment.

Extrapulmonary manifestations can affect nearly every organ.[22] Cardiac complications include thrombosis, myocardial infarction, mild to severe myocarditis[23] (in about 2% of healthy young patients), and arrhythmias. Neurologic complications can include myoclonus, seizures, delirium, and encephalitis. Loss of taste and smell appear to be locally mediated in the upper respiratory tract and not reflective of brain involvement. Renal damage is common, with about one third of the patients who require mechanical ventilation also requiring renal dialysis. Skin lesions can include maculopapular eruptions, urticarial lesions, and vesicles. Of hospitalized patients, about 15% require intensive care, about 12% require mechanical ventilation, and about 3 to 4% require renal dialysis. The severity of infections has decreased markedly with the advent of vaccinations, as well as inpatient and outpatient treatments (including remdesivir, anti-inflammatory medication, monoclonal antibodies, and antiviral agents).

TABLE 336-1 SYMPTOMS OF COVID-19 IN SYMPTOMATIC CASES

	APPROXIMATE % OF PATIENTS
Fever	70-90
Dry cough	60-85
Dyspnea	50-80
Changes in taste or smell	40-80
Fatigue	40-60
Gastrointestinal symptoms*	15-60
Myalgias	15-45
Chills	15-30
Headache	10-20
Sore throat	10-20
Rhinorrhea	5-10

*Including nausea, vomiting, diarrhea.
COVID-19 = coronavirus 19 disease.

DIAGNOSIS

The diagnosis of SARS-CoV-2 infection is made by the detection of viral elements by either a nucleic acid amplification test (NAAT; otherwise known as polymerase chain reaction [PCR] tests) or an antigen detection test.[24,25] Samples for testing can be collected from the nasopharynx, the anterior nares or mid-turbinate, oropharynx, and saliva. Estimates of sensitivity range from 80% to more than 95%, with false-negative tests more common before the onset of symptoms; test specificity is about 99%. Antigen-based testing is less sensitive than NAAT. For example, the rate of false-positive rapid antigen tests in one study of asymptomatic employees in a mass screening program was high (62%), but repeat testing significantly increased their sensitivity and specificity.[26,27] At-home testing kits using antigen-based testing are also available, although instructions must be followed to increase accuracy. Finally, patients who have recovered from COVID-19 may continue to shed inactive viral particles up to 90 days. Since inactive viral particles are not infectious, the U.S. Centers for Disease Control and Prevention (CDC) recommends a 5-day period of isolation after the onset of symptoms, but isolation can end without the need for repeat antigen or PCR testing if symptoms resolve.

The sensitivity and specificity of these tests also vary dramatically during the course of infection because of the concentration of viral material in the sample (Fig. 336-2). PCR can detect SARS-CoV-2 RNA for many days or even weeks after the person has recovered and is no longer infectious. For that reason, PCR should not be repeated in asymptomatic persons within 90 days of a confirmed SARS-CoV-2 infection. Since these tests do report replication-competent (viable) virus required for transmission, a positive rapid antigen test correlates with culture positivity only about 50% of the time, although a high PCR copy number reflected in a low number of cycles for detection (i.e., <30) is more likely to correlate with both a positive antigen test and the potential for SARS-CoV-2 transmission. However, since PCR cycles usually are not reported in a routine PCR test, the CDC recommends that isolation be guided by the maximum period of transmission (e.g., 5 days after the onset of symptoms).

Serologic tests, which can detect past infection or vaccination status, are of two types: tests that detect binding antibodies and tests that detect neutralizing antibodies. However, serologic testing is still not commercially available to measure neutralizing antibodies. In addition, serologic tests can detect IgM, IgG, IgA, or total antibodies, as well as IgG subclasses. Spike protein IgG can indicate either past infection or vaccination, whereas nucleocapsid IgG positivity is indicative of past infection since the current spike protein vaccines do not trigger this antibody. Antibody testing is not recommended for the diagnosis of acute infection but can be useful in confirming past infection when anti-nucleocapsid antibodies and anti-spike antibodies are detected. For example, a large U.S. seroprevalence survey

	Stage	Characteristics
	Asymptomatic/ presymptomatic infection	• Positive test for SARS-CoV-2 but no symptoms
~80%	Mild illness	• Varied symptoms (e.g., fever, cough, sore throat, taste/smell disturbance) but no shortness of breath or abnormal imaging
~80%	Moderate illness	• Spo_2 ≥94% and lower respiratory disease (clinical or imaging findings)
~15%	Severe illness	• Spo_2 <94%, Pao_2/Fio_2 <300, respiratory rate >30/min, or lung infiltrates >50%
~5%	Critical illness	• Respiratory failure, shock, and/or multiorgan dysfunction

Characteristics of and important lessons from the coronavirus disease 2019 [COVID-19] outbreak in China: summary of a report of 72 314 cases from the Chinese Center for Disease Control and Prevention. *JAMA*. 2020;323:1239-1242; and National Institutes of Health. NIH COVID-19 treatment guidelines. Clinical spectrum of SARS-CoV-2 infection. www.covid19treatmentguidelines.nih.gov/overview/clinical-spectrum/. Accessed April 25, 2022.)

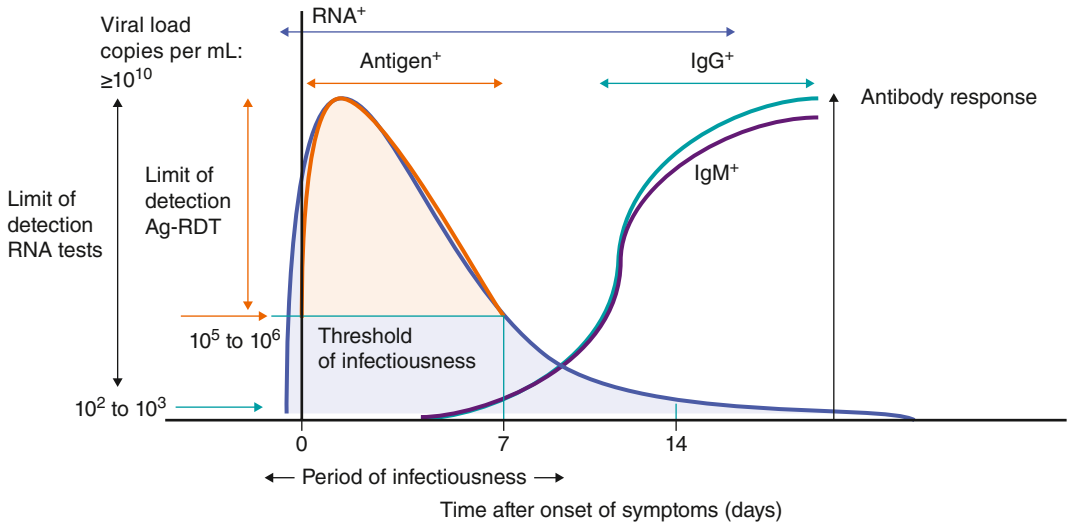

FIGURE 336-2. Timelines for optimal use of different tests for COVID-19 detection and host response. Antigen levels peak before day 4 and typically are undetectable by day 7, whereas antibody levels may not be detectable until about day 10. RNA, which is detectable by polymerase chain reaction testing, is more sensitive and long-lasting than is the detection of antigen. Ag-RDT = antigen-rapid detection test; Ig = immunoglobulin. (From Peeling RW, Heymann DL, Teo Y-Y, et al. Diagnostics for COVID-19: moving from pandemic response to control. *Lancet*. 2022;399:757-768.)

showed that almost 60% of adults and 75% of children under age 18 years had been exposed to the virus by February 2022.[28] However, serologic testing is not recommended to determine if a person is immune to SARS-CoV-2, either after infection or vaccination, because antibody titers may wane for a variety of reasons and do not reflect other potential and important immune responses, especially T-cell–mediated immunity. In addition, a positive test does not ensure immunity against reinfection and may provide a false sense of security.

Initial evaluation of symptomatic patients with SARS-CoV-2 infection and hypoxemia should include a chest radiograph or a computed tomographic (CT) scan to assess for the extent of pulmonary infiltrates. Chest radiographs may be normal in early or mild disease. Common abnormalities include ground-glass opacities and consolidation consistent with viral pneumonia (E-Figs. 72-1 to 72-6). Although chest CT may be more sensitive than plain chest radiography, chest CT is not recommended for screening or diagnosis since its findings can resemble other respiratory pathogens.[29]

Laboratory examination should include a complete blood count with differential and a metabolic profile. The measurement of serum levels of inflammatory markers (e.g., C-reactive protein, D-dimer, and ferritin) may have prognostic and therapeutic value and can be helpful in hospitalized patients at high risk of progression.[30] Common laboratory findings include lymphopenia, elevated aminotransferase levels, and elevated lactate dehydrogenase levels. Diagnostic tests such as a D-dimer test may be used to exclude deep venous thrombosis or pulmonary emboli, since clots have been an important consequence of severe SARS-CoV-2 infection.[31]

PROGNOSIS

In the first COVID-19 surge caused by the ancestral (Wuhan) strain in the pre-vaccine era, the infection fatality rate was under 1% for persons under age 65 years but increased to 15% for persons aged 85 years and older.[32] The severity of the infection has evolved as variants have appeared and as vaccinations have become available. With vaccination, the risk of hospitalization, critical illness, and death from COVID-19 is significantly decreased. For example, unvaccinated persons over age 65 years are 3.4 times more likely to be hospitalized with COVID-19 and 4.3 times more likely to die of COVID-19 than are vaccinated persons of the same age. The risk of hospitalization and mortality also have been lower with recent omicron variants than with earlier variants due to its inherently lower virulence.[33]

After recovering from COVID-19, most individuals have several months of protection from repeat infection. However, reinfection with SARS-CoV-2 has been increasingly reported,[34] either due to waning antibodies or the emergence of new variants against which antibodies do not work as well. Infections that overwhelm vaccination are referred to as breakthrough events. Reinfection and breakthrough infections have a much lower chance of progressing to hospitalization or death compared with primary infection or infection in those who remain unvaccinated.[35] For example, in a large analysis of over 1.2 million adults who completed primary vaccination by October 2021, the rate of severe COVID-19 breakthrough was 0.015% and the rate of COVID-19 death after a breakthrough was 0.0033%. Risk factors for severe outcome included over age 65 years, being immunosuppressed, and having four or more underlying comorbid conditions. These data have guided the public health community to target persons at risk of severe breakthroughs for booster vaccination and, if infected, for SARS-CoV-2 prophylaxis (e.g., with monoclonal antibodies) and antiviral treatment.

Most patients who have had COVID-19 recover completely,[36] but some patients experience prolonged symptoms or develop long-term effects.[37,38] This condition, which had been called long COVID, is now formally named post-acute sequelae of SARS-CoV-2 (PASC). The WHO defines PASC as symptoms that persist for at least 2 months after resolution of probable or confirmed acute SARS-CoV-2 infection (i.e., usually 3 months after the onset of COVID-19) and that cannot be explained by an alternative diagnosis. The CDC, by comparison, defines PASC as new, returning, or ongoing health problems 4 or more weeks after first being infected with SARS-CoV-2. Although PASC may be more common in patients who have severe COVID-19, even mild illness can lead to PASC. Risk factors for developing post-acute sequelae of SARS-CoV-2 include type 2 diabetes, SARS-CoV-2 RNAemia, and concomitant infections such as Epstein-Barr virus viremia[39] but not inflammatory markers or autoantibodies.[40] The most common symptoms include fatigue, headaches, attention disorders, anosmia, ageusia, loss of hair, persistent cough, chest pain, and memory loss.[41-43] Data suggest vaccination decreases the risk of long COVID.

COMMUNITY PREVENTION OF SARS-COV-2

As with other infectious diseases, SARS-CoV-2 prevention is best achieved by both vaccination (Chapter 337) and nonpharmacologic interventions. Prior to the availability of vaccines and monoclonal antibodies (for those who cannot respond to a vaccine), the safest behaviors include use of physical distancing, well-fitting masks, ventilation, and avoidance of indoor gatherings.[44-47] Observational data suggest that distancing at 1 meter reduces the risk of an infection by about 80%, with protection increasing as the distance is lengthened. Disposable surgical masks reduce infection by more than cloth masks, and N95, KN95, FFP2, or KF94 masks reduce the risk even more, with one-way masking serving as a form of self-protection.[48] Proper indoor air ventilation is an important mitigation procedure for SARS-CoV-2 and other respiratory pathogens.[49]

337 COVID-19 TREATMENT AND VACCINATION

RAJESH T. GANDHI AND KATHLEEN M. NEUZIL

TREATMENT OF INFECTED PERSONS

GENERAL PRINCIPLES

The approach to treating coronavirus-2019 disease (COVID-19) must first consider the severity of the patient's disease, which can range from mild to moderate respiratory or systemic symptoms, to severe disease (i.e., dyspnea, tachypnea, and hypoxia), to critical illness (i.e., respiratory failure, shock, and/or multiorgan failure; see Fig. 336-1). The second consideration is the phase of illness. The third consideration is the type of intervention: antiviral therapy, immunomodulatory medications, combination therapy, and therapies directed at preventing or treating complications, such as thrombosis.

Overview of Treatment

The pathogenesis that drives the different phases of the illness also informs treatment decisions (Fig. 337-1).[1] Viral replication is most active early in disease, whereas excess inflammation occurs later in the course of disease. Regardless of the phase of illness, it is safe to continue angiotensin-converting enzyme 2 (ACE2) inhibitors, angiotensin-receptor blockers, and therapeutic nonsteroidal anti-inflammatory drugs.

OUTPATIENTS WITH MILD TO MODERATE COVID-19

Most patients with mild to moderate COVID-19 will recover with supportive care, such as hydration, antipyretics, and analgesics.[2] However, close monitoring for clinical worsening is mandatory, particularly for patients who are at increased risk for progression, such as patients who are older, who have certain chronic conditions (e.g., cardiovascular disease, chronic lung disease, obesity, immunocompromising conditions), or who are taking immunosuppressive medications. Worsening shortness of breath, which typically occurs about 1 week after the onset of symptoms, or other severe or progressive symptoms should prompt in-person evaluation. Patients with COVID-19 may deteriorate rapidly, and hospitalization is indicated for monitoring and treatment if patients develop progressive dyspnea, weakness, lethargy, or confusion or if they become tachypneic or hypoxic or have a markedly abnormal chest radiograph.

Anti–SARS-CoV-2 Monoclonal Antibodies and Passive Immunity

Passive immunity can be induced by monoclonal antibodies that bind to the SARS-CoV-2 spike protein, block viral entry into cells, and thereby reduce replication. Monoclonal antibodies can result in more rapid viral clearance and reduce rates of hospitalization or death by approximately 70 to 85% when given within a few days of the onset of symptoms[A1–A3] to outpatients who have mild to moderate COVID-19 and are at high risk for progression (see Fig. 337-1), provided that they are infected with susceptible viral variants. However, antibodies that were successful against earlier SARS CoV-2 variants have less activity against newer variants; as a result of changing variants, anti–SARS-CoV-2 monoclonal antibodies are currently not authorized for treatment or prophylaxis in the United States. The decision to use antibodies and the doses among them should be guided by data on current variants and their susceptibility.

Convalescent plasma, which is derived from patients who previously have been infected, has shown mixed results. In one study, it reduced the risk of hospitalization in unvaccinated outpatients treated with 8 days of symptoms,[A4] but other studies showed no benefit.[A5] Currently it is authorized for use in immunocompromised individuals, but it should only be considered if the plasma is likely be active against the circulating variant.

Antiviral Medications

Antiviral medications are useful in high-risk patients who are early in their disease course (Fig. 337-2). However, none of the available drugs are currently authorized for lower risk patients.

Molnupiravir, which is an oral inhibitor of SARS-CoV-2 replication, induces mutations that compromise the virus's viability. In nonhospitalized adults who have had 5 or fewer days of mild or moderate COVID-19 symptoms plus at least one risk factor for developing severe COVID-19, molnupiravir (800 mg twice daily for 5 days) reduces the risk of hospitalization or death by about 30%.[A6] To date, the drug appears to be active against all variants, at least through Omicron.

Nirmatrelvir is an oral protease inhibitor that is coadministered with ritonavir to boost its blood level by inhibiting its metabolism by the cytochrome P-450 system. In unvaccinated nonhospitalized patients who have COVID-19 with a high risk of clinical progression and who are treated within 5 days of the onset of symptoms, nirmatrelvir/ritonavir can reduce the risk of hospitalization or death by about 90%.[A7]

Remdesivir, which is a nucleotide pro-drug, binds to the SARS-CoV-2 RNA polymerase, acts as a chain terminator, and thereby inhibits RNA synthesis and viral replication. In high-risk nonhospitalized patients treated within 7 days of the onset of symptoms, remdesivir (200 mg on day 1 and 100 mg on days 2 and 3) for 3 days can reduce hospitalization by 87%, even though it does not reduce nasopharyngeal SARS-CoV-2 levels.[A8]

Currently nirmatrelvir/ritonavir is typically the first choice in most high-risk patients. In a patient who cannot receive nirmatrelvir/ritonavir because of drug-drug interactions, remdesivir is usually the second choice. When remdesivir is not feasible or appropriate, molnupiravir should be considered.

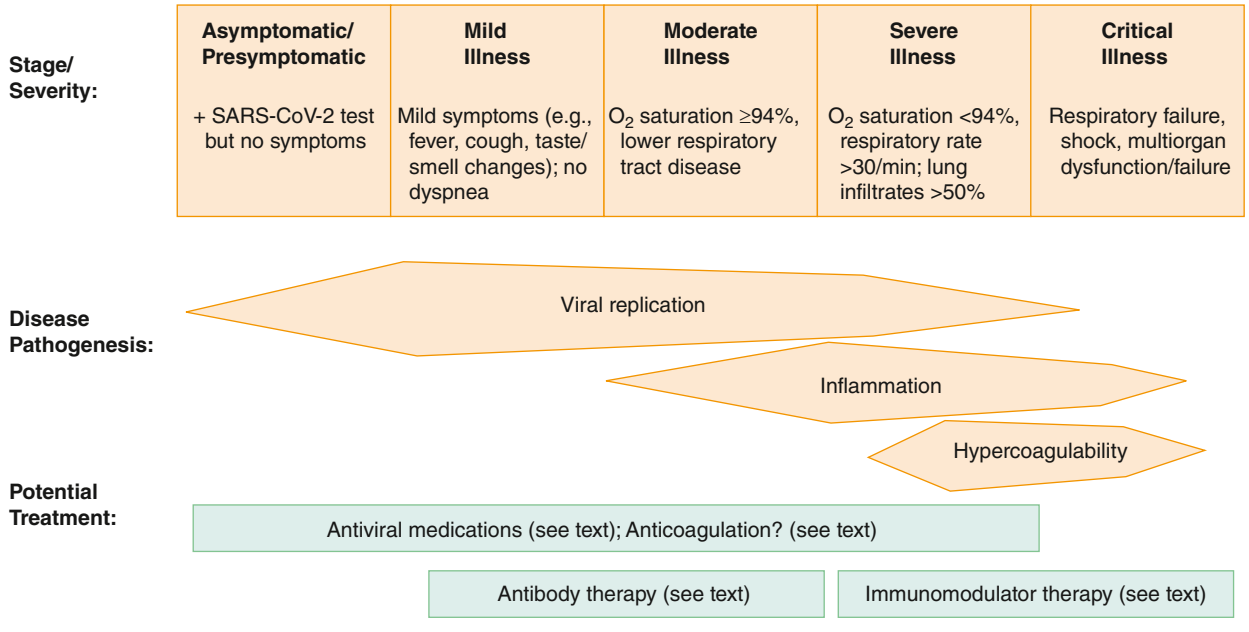

FIGURE 337-1. **Disease pathogenesis and treatment across the COVID-19 disease spectrum.** O_2 = oxygen; SARS-CoV-2 = severe acute respiratory syndrome coronavirus-2. (Adapted from Gandhi RT, Lynch JB, del Rio C. Mild or moderate Covid-19. *N Engl J Med*. 2020;383:1757-1766.)

ABSTRACT

Treatment for COVID-19 depends on the severity of the infection, the patient's characteristics, and the phase of illness. For nonhospitalized patients at high risk of progression soon after the onset of symptoms, several antiviral medications are efficacious. For patients who are hospitalized with COVID-19 and who require oxygen support, immunomodulators are the mainstay of therapy. Anticoagulation is indicated for some patients with severe COVID-19. Safe, immunogenic, and efficacious COVID-19 vaccines are approved for persons ages 6 months and older, with vaccine schedules differing by age and risk groups. Newer bivalent vaccines that contain the original and a variant strain are recommended for persons ages 5 years and older. Vaccine formulations and recommendations for use will continue to evolve over time.

Other Outpatient Medications

The role of other therapies, such as inhaled budesonide (800 μg twice daily for 14 days)[A9] and fluvoxamine, is uncertain. Ivermectin has not been shown to be of benefit. Neither anti-platelet therapy with aspirin nor anticoagulant therapy with apixaban is recommended in outpatients who do not have other indications for their use.

TREATMENT OF HOSPITALIZED PATIENTS WITH SEVERE OR CRITICAL COVID-19

Hospitalized patients with COVID-19 benefit from selected medications and from careful attention to oxygenation, intensive care, and organ support.[3] Clinicians should follow the latest guidelines (see https://www.covid19treatmentguidelines.nih.gov/about-the-guidelines/whats-new/ and https://www.idsociety.org/practice-guideline/covid-19-guideline-treatment-and-management/).

Medications

Antiviral Medications

Remdesivir (200-mg infusion on day 1 followed by a 100-mg infusion daily) appears to speed the time to recovery and improve outcomes, at least when given within 10 days of the onset of symptoms to patients who require supplemental oxygen but who are not yet intubated.[A10] Five days of therapy is as good a 10-day course. However, studies suggest that the mortality benefit of remdesivir in hospitalized paatients with COVID-19 is small and limited to patients who are not initially ventilated.[A11] Currently, guidelines in some countries, such as the United States,[4] recommend the use of remdesivir in patients with severe COVID-19 because it can hasten clinical recovery. The World Health Organization guidelines also recommend the use of remdesivir.[5]

Corticosteroids

Dexamethasone (6 mg/day, orally or intravenously, for up to 10 days or until hospital discharge if sooner) reduces mortality in hospitalized patients who require supplemental oxygen but not mechanical ventilation by nearly 20% and in patients who require mechanical ventilation by about 35%.[A12] However, it is not beneficial and may harm patients who do not require oxygen. As a result, it is recommended in all patients who require oxygen therapy but not in other patients. If dexamethasone is not available, prednisone (40 mg/day), methylprednisolone (32 mg/day), or hydrocortisone (160 mg/day) may be used.[A13]

Other Anti-Inflammatory Agents

Elevated interleukin (IL)-6 levels are associated with worse outcomes in patients with COVID-19, and IL-6 blockade with tocilizumab (8 mg/kg, up to 800 mg, intravenous infusion given once or twice in adults) reduces in-hospital mortality by about 15% in patients who are rapidly deteriorating, have excess inflammation, and are receiving corticosteroids.[A14] As a result, tocilizumab is recommended in combination with corticosteroids for recently hospitalized patients who have progressive COVID-19, rapidly worsening hypoxia, and evidence of excess inflammation or who have just been transferred to the intensive care unit. Sarilumab, another IL-6 blocker, also appears to confer benefit, although the data are more limited.[A15] IL-6 blockers should be used with caution or avoided in patients who are significantly immunosuppressed, are at high risk for gastrointestinal perforation, or who have uncontrolled serious infections other than COVID-19.

Janus kinase inhibitors reduce inflammation by reducing the production of cytokines. The Janus kinase inhibitors baricitinib (4 mg/day orally for up to 14 days or until hospital discharge)[A16] and tofacitinib (10 mg orally twice daily for up to 14 days or until hospital discharge)[A17] improve outcomes in patients who are hospitalized with COVID-19 pneumonia when added to corticosteroids. In one study, for example, baricitnib reduced mortality by day 28 by about 40% in hospitalized patients with COVID-19 pneumonia and elevation of one or more inflammatory markers (e.g., levels of C-reactive protein, D-dimer, lactate dehydrogenase, or ferritin).

Guidelines for Combined Antiviral and Anti-Inflammatory Therapies

Current guidelines recommend remdesivir plus dexamethasone in hospitalized COVID-19 patients who require supplemental oxygen but not mechanical ventilation. In a patient who requires only minimal amounts of oxygen, remdesivir alone may be used.

In hospitalized patients with progressive COVID-19, escalating oxygen requirements, rapidly worsening hypoxia, and evidence of excess inflammation or in patients who have just been transferred to an intensive care unit, augmented immunomodulation should combine dexamethasone with either an IL-6 antagonist (e.g., tocilizumab or, if unavailable, sarilumab) or a Janus kinase inhibitor (baricitinib or, if unavailable, tofacitinib). IL-6 antagonists have not been compared against Janus kinase inhibitors.

Passive Immunity

Monoclonal antibodies have had mixed success in hospitalized patients with COVID-19, even when they effectively target the viral variant. In one study, monoclonal antibodies were associated with clinical benefit in hospitalized patients who had not developed an endogenous antibody response as evidenced by their being seronegative for antispike protein antibodies.[A18] However, current variants are not expected to be susceptible to anti–SARS-CoV-2 monoclonal anitbodies, so antibodies are not being used at this time. Neither convalescent serum nor hyperimmune globulin is beneficial in unselected inpatients.

Anticoagulation

Because of the high rate of arterial and venous large vessel and microvascular thrombosis in hospitalized patients with COVID-19,[6] prophylactic anticoagulation with low-molecular-weight heparin is recommended (see Table 70-2),[7] unless contraindicated because of ongoing bleeding or severe thrombocytopenia. Anticoagulation with therapeutic doses of heparin is considered only in the subset of patients who are hospitalized with COVID-19 pneumonia, require conventional oxygen therapy, have elevated D-dimer levels, and are not at increased risk for bleeding.

Other Medications

Hydroxychloroquine, azithromycin, colchicine, interferon-β, and lopinavir/ritonavir are ineffective in hospitalized patients. Ivermectin has not been shown to

TABLE 337-1 CHARACTERISTICS OF COVID-19 VACCINES AUTHORIZED FOR USE IN THE UNITED STATES AND SPECIFIC VACCINE RECOMMENDATIONS, JULY 2022

	PFIZER-BIONTECH mRNA	MODERNA mRNA	JANSSEN AD26 VECTOR	NOVAVAX PROTEIN
Vaccine type	mRNA	mRNA	Adenovirus vector	Adjuvanted protein subunit
Target protein	Prefusion stabilized full- length S glycoprotein	Prefusion stabilized full-length S glycoprotein	Prefusion stabilized full-length S glycoprotein	Prefusion stabilized full-length S glycoprotein
Age indications	≥6 months	≥6 months	≥18 years	≥12 years
Dose	30 μg for age ≥12 years (primary series and booster) 10 μg for age 5-11 years (primary series and booster) 3 μg for age 6 months through 4 years (three-dose primary series)	100 μg primary series for ≥12 years 50 μg booster dose for ≥18 years 50 μg primary series for age 6-11 years 25 μg primary series for 6 months through 5 years (two-dose primary series)	5×10^{10} viral particles (0.5 mL)	5 μg antigen + 50 μg Matrix-M adjuvant
Dosage	0.3 mL	0.5 mL	0.5 mL	0.5 mL
Number of doses, interval, primary series	Ages 5 and over: two doses, 3-8 weeks apart Ages 6 months through 4 years: three doses, 3-8 weeks apart for doses 1 to 2 and at least 8 weeks for doses 2 to 3	Ages 6 months and older: two doses, 4-8 weeks apart	One dose	Two doses, 3-8 weeks apart
Adults who are moderately or severely immunocompromised persons	Three-dose primary series and mRNA booster doses	Three-dose primary series and mRNA booster doses	Two-dose primary series and mRNA booster doses	Two doses, 3 weeks apart and mRNA booster doses
Interval between primary and booster doses, adults	At least 5 calendar months after completing the primary series		At least 8 weeks after the first dose	Not approved for booster dose
Bivalent booster dose **should** be administered to:	All persons age 5 years and older		n/a	n/a
Interval between monovalent and bivalent booster dose	At least 2 calendar months after primary series or monovalent booster dose		n/a	n/a
Coadministration with other vaccines	COVID-19 vaccine and other vaccines may be administered on the same day, as well as any interval without respect to timing.			
Person with prior or current COVID-19	COVID-19 vaccines can be given safely to people with prior SARS-CoV-2 infection. Defer vaccination until person has recovered from the acute illness and criteria have been met for them to discontinue isolation.			
Persons who received monoclonal antibodies or convalescent plasma for COVID-19 treatment	COVID-19 vaccination can be given at any interval following receipt of passive antibody therapy. Persons should wait 2 weeks after COVID-19 vaccination before receiving tixagevimab/cilgavimab for preexposure prophylaxis.			
Interchangeability of primary series	The same vaccine product should be used for all doses in the primary series. If mixed primary series is inadvertently administered, the series is complete and doses do not need to be repeated. mRNA vaccines (Moderna, Pfizer-BioNTech) are preferred in most situations over the Janssen COVID-19 vaccine. Primary series and additional primary doses (for moderately and severely compromised people) should be with the same mRNA vaccine product. In exceptional situations, such as a contraindication to a second dose of mRNA vaccine or when a previous dose product cannot be determined or is not available, another FDA-approved or FDA-authorized COVID-19 vaccine may be used			

COVID = coronavirus disease; FDA = U.S. Food and Drug Administration; mRNA = messenger RNA; SARS-CoV-2 = severe acute respiratory syndrome coronavirus-2.

confer benefit. Pegylated interferon lambda may reduce the risk of an emergency department visit or hospitalization among vaccinated outpatients who are treated within 7 days after the onset of symptoms [A19] but is currently experimental. Because clinical trials are ongoing, guidelines (https://www.covid19treatmentguidelines.nih.gov/about-the-guidelines/whats-new/ and https://www.idsociety.org/practice-guideline/covid-19-guideline-treatment-and-management/) should be consulted for the latest evidence and recommendations.[8]

General Care

Organ Support during Critical Illness

In addition to pneumonia, COVID-19 is associated with a broad range of complications (Chapter 336), including respiratory failure (Chapter 90), shock (Chapter 92), heart failure (Chapters 45 and 46), acute renal injury (Chapter 106), and hepatic failure (Chapter 140). Management is largely in accord with strategies developed for other critically ill patients. For example, treatment of shock, hypoxemic respiratory failure, and other complications is guided by general principles of critical care. High-flow oxygen therapy through a nasal cannula can significantly reduce the need for mechanical ventilation.[A20] Awake prone positioning may sometimes be useful (https://www.covid19treatmentguidelines.nih.gov/about-the-guidelines/whats-new/).

Other Complications

Coinfection with bacterial, fungal, or other viral pathogens is relatively uncommon with initial COVID-19 infection,[9] so empirical therapy for other infections is generally not warranted. However, sudden respiratory or hemodynamic deterioration, especially in a patient who has been on a ventilator for an extended period of time (Chapter 85), should raise concern about a superimposed bacterial infection or fungal pneumonia (especially aspergillosis [Chapter 311] or mucormycosis [Chapter 312]), acute heart failure, or a pulmonary embolus.

Multisystem Inflammatory Syndrome

Multisystem inflammatory syndrome is a postinflammatory condition that is seen mostly in a small proportion of children who may present with fever, elevated laboratory markers of inflammation, and multisystem organ involvement (e.g., cardiac dysfunction, gastrointestinal symptoms or signs, skin rash, and conjunctival abnormalities). Adults may develop a similar syndrome. Treatment for adults has not been well studied, so recommendations are generally extrapolated from those for children (https://www.covid19treatmentguidelines.nih.gov/management/clinical-management/hospitalized-pediatric-patients--therapeutic-management-of-mis-c/).

PREVENTION

TREATMENT OF CONTACTS OF INFECTED PERSON

Anti–SARS-CoV-2 monoclonal antibodies can prevent symptomatic COVID-19 among persons who are exposed to variants against which the antibodies are effective. Currently, however, existing antibodies for postexposure prophylaxis are not effective against the latest circulating viral variants. Preexposure prophylaxis with the combination of two long-acting anti–SARS-CoV-2 monoclonal antibodies, tixagevimab plus cilgavimab, reduced the incidence of symptomatic COVID-19 by about 80% in unvaccinated individuals.[A21] This combination had been authorized for preexposure prophylaxis in immunocompromised individuals who may not have an adequate immune response to COVID-19 vaccination or in the rare individual who cannot receive a COVID-19 vaccine due to a serious adverse event. However, current viral variants are not expected to be susceptible, and the authorization for these antibodies has been withdrawn.

VACCINATION

Vaccines for SARS-CoV-1 target the S protein, which is a trimeric fusion protein with a metastable prefusion conformation (Table 337-1). Four safe and efficacious COVID-19 vaccines are currently approved in the United States, but these vaccines have not been directly compared against each other.

A two-dose regimen of mRNA vaccines manufactured by Pfizer-BioNTech (3 weeks apart) or Moderna (4 weeks apart) was up to 95% efficacious over the short term against the original SARS-CoV-2 strain for preventing symptomatic, laboratory-confirmed COVID-19 in persons who did not have evidence of previous SARS-CoV-2 infection.[10,A22,A23] Vaccines also have been effective against serious outcomes of COVID-19 caused by viral variants, although their efficacy has declined for newer variants.[A24,A25] Vaccines are similarly effective, regardless of age, gender, ethnicity, or medical comorbid conditions, but they have not been extensively evaluated in immunocompromised patients.

Two adenovirus vector vaccines (Astra-Zeneca in a two-dose regimen 1 month apart or Janssen single dose) were about 70% protective against clinical infection due to the original vaccine strains regardless of age, sex, ethnicity, or underlying medical condition. They also appear to be 90% or more effective for preventing hospitalizations and deaths, although this effectiveness has declined for newer variants.[A26] In the United States, the Janssen vaccine is the only authorized adenovirus vector vaccine, and mRNA vaccines are preferred over Janssen COVID-19 vaccine for the primary series and booster doses.

A two-dose recombinant S protein vaccine with a saponin-based adjuvant (Novavax) is well-tolerated and has over 90% efficacy against symptomatic COVID-19 and close to 100% efficacy against severe disease.[A27] The vaccine is approved in the United States for persons ages 12 years and over as a two-dose primary series. An ASO3-adjuvanted recombinant S protein-based vaccine (Sanofi Pasteur) provides robust neutralizing antibody responses in adults, and the two-dose product is in late stages of clinical testing.

In the United States, the Pfizer-BioNTech and Moderna COVID-19 vaccines are approved in children and adolescents, beginning at 6 months of age. For children and adolescents ages 5 to 15 years[A28,A29] these vaccines are approximately 90% efficacious for preventing symptomatic, laboratory-confirmed COVID-19 in the short term. In younger children, for whom the mRNA COVID-19 vaccines were tested predominantly during circulation of variant strains, antibody levels and efficacy are similar to what is seen for similar variants in older age groups.[A30] Pediatric recommendations for dosing differ by age and manufacturer (see Table 337-1).

Over time and with new viral variants, the effectiveness of vaccines declines, more so in older adults and immunocompromised individuals, and in terms of lost protection against any infection rather than severe infection that requires hospitalization.[11] As a result, additional booster doses of mRNA vaccines are recommended to provide additional protection, including in persons who have had COVID-19.[A31,12–17] With continuing evolution of viral strains, COVID-19 vaccines have been formulated to include viral variants. The first approved bivalent formulations were mRNA formulations containing both the ancestral strain and an Omicron BA4/5 variant strain. In 2022, bivalent mRNA COVID-19 vaccine booster doses were recommended for persons ages 5 years and older, administered 2 or more months after completing the primary series or after receipt of a monovalent booster dose. Subsequently, such vaccines have been shown to improve protection against clinical illness. COVID-19 vaccines will continue to be updated on a periodic basis as directed by the Food and Drug Administration.[18,19]

Adverse Effects of Vaccination

Anaphylaxis occurs in approximately two to five people per million after COVID-19 vaccination. Most side effects are self-limiting, with pain at the injection site the most frequent and severe local reaction. Reactions tend to be more common in younger than in older age persons, and for the second dose as compared to the first.

In about 4 per 1 million persons vaccinated with the Janssen COVID-19 vaccine, a thrombosis with thrombocytopenia syndrome, with thrombosis in unusual sites such as the central venous system and splanchnic vessels, can develop approximately 1 to 2 weeks after vaccination.[20,21] Guillain-Barré syndrome, seen predominantly with the Janssen COVID-19 vaccine,[22] is also rare, with the highest risk being 16 cases per 1 million doses among 50- to 64-year-old males. Myocarditis and pericarditis can develop, principally in adolescents and young adults after either of the two mRNA COVID-19 vaccines or after the Novavax protein vaccine[23]; the clinical course is generally mild to moderate and responds to conservative treatment.[24]

Vaccine Policy

Given critical global needs, efforts continue to develop, refine, and manufacture COVID-19 vaccines at greater scale. Second-generation vaccines that increase the breadth and durability of immunity are a high priority, including vaccines against variant strains and targets other than the S protein. By June 2022, when about 80% of eligible American adults had at least one dose of a COVID-19 vaccine, only about 16% of residents of low-income countries had received one dose. Even in the United States, the poor uptake in certain segments of the population has slowed efforts to control the pandemic. Additional investments in implementation in science and public health will be needed to overcome vaccine hesitancy, to increase confidence in vaccines, and to enhance public health communications.

MEASLES

MARTIN G. OTTOLINI

DEFINITION

The term *measles* is applied most appropriately to "rubeola" (also known as "morbilli"), an extremely contagious, prolonged respiratory and systemic viral illness characterized by high fever, an erythematous maculopapular rash, cough, coryza, and conjunctivitis. A member of the family Paramyxoviridae, within the genus *Morbillivirus*, the measles virus exhibits at least 24 distinct genotypes but behaves as a single serotype because natural infection or adequate immunization confers broad protection against all types.[1,2]

EPIDEMIOLOGY

Measles may be the most contagious pathogen known to humans, and it has no other reservoir. Its basic reproduction number, the R_0, which represents the number of naïve contacts potentially infected by exposure to one contagious individual, has been estimated to be 12 to 18,[3] an R_0 far higher than the R_0 of two to three for Ebola (Chapter 351) and influenza (Chapter 332). Key challenges to control of the spread of measles include the immunization status of a population, their density, and the influence of migration and travel.

In the 1950s and early 1960s, measles was ubiquitous in the United States, with more than 500,000 cases reported annually, and nearly everyone was infected by adulthood. By 2000, a two-dose, live-attenuated vaccine led to endemic measles being declared "eliminated" from the United States. From 2001 to 2016, a median of 28 imported measles case were reported annually in the United States. More recently, measles cases in the United States increased dramatically, peaking in 2019 with 1282 confirmed cases, mostly in regional outbreaks in close-knit and underimmunized communities exposed to measles brought back by international travelers.[4,5] However, the number of confirmed cases dropped dramatically to just 13 in 2020, an unexpected benefit of the restriction of social interactions and use of masks in response to the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) coronavirus disease 2019 (COVID-19) pandemic (Chapters 335, 336, and 337). This benefit may be short-lived because the pandemic's disruptions also resulted in reductions in routine immunizations by 22% in children ages 12 to 23 months and 63% in children aged 2 to 8 years. Though rates rose quickly after the lifting of the most severe SARS-CoV-2 restrictions, data so far have not shown an effective "catch up" of the deficits encountered.[6]

The global incidence of measles decreased from an estimated 145 cases per million population in 2000 to just 18 per million in 2016, subsequently rose to 120 per million in 2019, then declined again to 17 per million in 2021 during the height of the COVID-19 pandemic.[7] Annual global measles deaths decreased from over 500,000 in 2000 to 109,000 in 2017, rose to over 200,000 in 2019, and were 128,000 in 2021. The Americas are no longer free from endemic measles transmission, and the ambitious goal of eliminating measles in 5 of 6 world regions by 2020 has not been met.

Global protection by at least one measles immunization flattened after 2010, at a rate of about 86% until it fell to 81% in 2021, though the numbers of individuals receiving the required two immunizations rose from 48% in 2012 to 71% in 2019. In 2021, 47% of all WHO member countries achieved the goal of greater than 90% first-dose coverage, but an estimated 24.7 million children did not receive even an initial measles vaccine. About 60% of the missed initial doses occurred in just 10 countries, including Nigeria, India, Democratic Republic of the Congo, Ethiopia, Indonesia, Pakistan, Philippines, Angola, Brazil, and Tanzania.

Measles also can be associated with long-term complications. For example, the country of Georgia has suffered from endemic measles for years, with widespread outbreaks in 2004-2005 and 2013-2015. Between 2008 and 2017, 16 confirmed survivors developed devastating subacute sclerosing panencephalitis,[8] 92% of whom were children infected prior to 2 years of age, at a mean interval of 6 years after the infection. Other than COVID-19, measles is the fourth leading worldwide cause of death due to infectious disease, following only tuberculosis (Chapter 299), HIV/AIDS (Chapter 353), and malaria (Chapter 316).

PATHOBIOLOGY

Measles virus is spread very effectively by contact with large droplets or inhalation of aerosolized small droplets, which can remain suspended for hours after an infected individual has exited. Unlike other paramyxoviruses, which primarily infect and inflame respiratory epithelia, measles virus targets the immune system. Measles virus initially infects cells in the respiratory tract or conjunctiva, then migrates to regional lymph nodes where it infects CD150/SLAM1-expressing T and B cells.[9] Infected mononuclear cells then travel to other lymphoid tissues, including the spleen, tonsils, and other lymph nodes to propagate infection. Virus may enter the central nervous system (CNS) through infected lymphocytes, although the exact mechanism remains unclear. Systemic infection of the gastrointestinal (GI) system, kidney, liver, and skin occurs by circulation of infected immune cells. Measles virus later infects the respiratory epithelium through the Nectin-4 receptor, spreads from cell to cell to cause damage and sloughing, and then is expelled as infectious droplets by coughing to repeat the cycle.

Measles virus initially evades immune recognition by inhibiting type 1 interferons, so extensive viral replication and systemic spread precedes clinical disease. The buccal mucosal lesions (Koplik spots) and the classic rash result from infection of capillary endothelium by measles virus, with syncytial cell formation as well as local production of nitrous oxide and tumor necrosis factor-α. Measles virus–specific T-cell host-immune responses lead to eventual necrosis of infected cells with viral clearance. Poor measles virus–specific T-cell responses are observed in individuals who are severely malnourished and immunocompromised, with reduced cellular necrosis and delayed viral clearance, thereby explaining their less obvious but prolonged skin changes.

The most dramatic aspect of measles virus infection may be its transient yet profound suppression of the immune system, possibly by targeting CD150(SLAM)-expressing cells. While inducing a cytotoxic T-cell response that clears infected cells and induces measles virus–specific memory B cells, measles virus concurrently depletes subsets of both regional and circulating T and B cells, with a loss of immune memory. The depletion of lymphocytes in gut and respiratory epithelium leads to increased morbidity and mortality from other infections and explains the increase in all-cause mortality for an after-measles infection.

CNS involvement includes several clinicopathologic syndromes. The mechanism of viral entry into the CNS is poorly understood, because human neurons do not usually express the most common receptors for measles virus (SLAM or Nectin-4), though entry may be facilitated by viral binding to Nectin-4–positive nasal or meningeal epithelial cells adjacent to neuronal tissue.[10] Infection can

MEASLES

MARTIN G. OTTOLINI

DEFINITION

The term *measles* is applied most appropriately to "rubeola" (also known as "morbilli"), an extremely contagious, prolonged respiratory and systemic viral illness characterized by high fever, an erythematous maculopapular rash, cough, coryza, and conjunctivitis. A member of the family Paramyxoviridae, within the genus *Morbillivirus*, the measles virus exhibits at least 24 distinct genotypes but behaves as a single serotype because natural infection or adequate immunization confers broad protection against all types.[1,2]

EPIDEMIOLOGY

Measles may be the most contagious pathogen known to humans, and it has no other reservoir. Its basic reproduction number, the R_0, which represents the number of naïve contacts potentially infected by exposure to one contagious individual, has been estimated to be 12 to 18,[3] an R_0 far higher than the R_0 of two to three for Ebola (Chapter 351) and influenza (Chapter 332). Key challenges to control of the spread of measles include the immunization status of a population, their density, and the influence of migration and travel.

In the 1950s and early 1960s, measles was ubiquitous in the United States, with more than 500,000 cases reported annually, and nearly everyone was infected by adulthood. By 2000, a two-dose, live-attenuated vaccine led to endemic measles being declared "eliminated" from the United States. From 2001 to 2016, a median of 28 imported measles case were reported annually in the United States. More recently, measles cases in the United States increased dramatically, peaking in 2019 with 1282 confirmed cases, mostly in regional outbreaks in close-knit and underimmunized communities exposed to measles brought back by international travelers.[4,5] However, the number of confirmed cases dropped dramatically to just 13 in 2020, an unexpected benefit of the restriction of social interactions and use of masks in response to the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) coronavirus disease 2019 (COVID-19) pandemic (Chapters 335, 336, and 337). This benefit may be short-lived because the pandemic's disruptions also resulted in reductions in routine immunizations by 22% in children ages 12 to 23 months and 63% in children aged 2 to 8 years. Though rates rose quickly after the lifting of the most severe SARS-CoV-2 restrictions, data so far have not shown an effective "catch up" of the deficits encountered.[6]

The global incidence of measles decreased from an estimated 145 cases per million population in 2000 to just 18 per million in 2016, subsequently rose to 120 per million in 2019, then declined again to 17 per million in 2021 during the height of the COVID-19 pandemic.[7] Annual global measles deaths decreased from over 500,000 in 2000 to 109,000 in 2017, rose to over 200,000 in 2019, and were 128,000 in 2021. The Americas are no longer free from endemic measles transmission, and the ambitious goal of eliminating measles in 5 of 6 world regions by 2020 has not been met.

Global protection by at least one measles immunization flattened after 2010, at a rate of about 86% until it fell to 81% in 2021, though the numbers of individuals receiving the required two immunizations rose from 48% in 2012 to 71% in 2019. In 2021, 47% of all WHO member countries achieved the goal of greater than 90% first-dose coverage, but an estimated 24.7 million children did not receive even an initial measles vaccine. About 60% of the missed initial doses occurred in just 10 countries, including Nigeria, India, Democratic Republic of the Congo, Ethiopia, Indonesia, Pakistan, Philippines, Angola, Brazil, and Tanzania.

Measles also can be associated with long-term complications. For example, the country of Georgia has suffered from endemic measles for years, with widespread outbreaks in 2004-2005 and 2013-2015. Between 2008 and 2017, 16 confirmed survivors developed devastating subacute sclerosing panencephalitis,[8] 92% of whom were children infected prior to 2 years of age, at a mean interval of 6 years after the infection. Other than COVID-19, measles is the fourth leading worldwide cause of death due to infectious disease, following only tuberculosis (Chapter 299), HIV/AIDS (Chapter 353), and malaria (Chapter 316).

PATHOBIOLOGY

Measles virus is spread very effectively by contact with large droplets or inhalation of aerosolized small droplets, which can remain suspended for hours after an infected individual has exited. Unlike other paramyxoviruses, which primarily infect and inflame respiratory epithelia, measles virus targets the immune system. Measles virus initially infects cells in the respiratory tract or conjunctiva, then migrates to regional lymph nodes where it infects CD150/SLAM1-expressing T and B cells.[9] Infected mononuclear cells then travel to other lymphoid tissues, including the spleen, tonsils, and other lymph nodes to propagate infection. Virus may enter the central nervous system (CNS) through infected lymphocytes, although the exact mechanism remains unclear. Systemic infection of the gastrointestinal (GI) system, kidney, liver, and skin occurs by circulation of infected immune cells. Measles virus later infects the respiratory epithelium through the Nectin-4 receptor, spreads from cell to cell to cause damage and sloughing, and then is expelled as infectious droplets by coughing to repeat the cycle.

Measles virus initially evades immune recognition by inhibiting type 1 interferons, so extensive viral replication and systemic spread precedes clinical disease. The buccal mucosal lesions (Koplik spots) and the classic rash result from infection of capillary endothelium by measles virus, with syncytial cell formation as well as local production of nitrous oxide and tumor necrosis factor-α. Measles virus–specific T-cell host-immune responses lead to eventual necrosis of infected cells with viral clearance. Poor measles virus–specific T-cell responses are observed in individuals who are severely malnourished and immunocompromised, with reduced cellular necrosis and delayed viral clearance, thereby explaining their less obvious but prolonged skin changes.

The most dramatic aspect of measles virus infection may be its transient yet profound suppression of the immune system, possibly by targeting CD150(SLAM)-expressing cells. While inducing a cytotoxic T-cell response that clears infected cells and induces measles virus–specific memory B cells, measles virus concurrently depletes subsets of both regional and circulating T and B cells, with a loss of immune memory. The depletion of lymphocytes in gut and respiratory epithelium leads to increased morbidity and mortality from other infections and explains the increase in all-cause mortality for an after-measles infection.

CNS involvement includes several clinicopathologic syndromes. The mechanism of viral entry into the CNS is poorly understood, because human neurons do not usually express the most common receptors for measles virus (SLAM or Nectin-4), though entry may be facilitated by viral binding to Nectin-4–positive nasal or meningeal epithelial cells adjacent to neuronal tissue.[10] Infection can

ABSTRACT

Measles is an extremely contagious and prolonged respiratory and systemic viral illness characterized by high fever, an erythematous maculopapular rash, a croupy cough, coryza, and conjunctivitis. Measles infects and depletes the immune system, so patients have greater susceptibility to other pathogens long after recovery. Complications include primary viral and secondary bacterial pneumonia, otitis media, and more rarely encephalitis, a prolonged debilitating diarrhea, and corneal scarring. A small percentage of patients will develop a relentlessly progressive and fatal panencephalitis years after recovery. Vitamin A supplementation may reduce the overall morbidity and mortality, which can be as high as 30% in malnourished populations. It should be given on the first and second days of illness and repeated at 4 to 6 weeks if abnormal ophthalmic findings are present. A live attenuated vaccine has been available since the late 1960s, and a two-immunization strategy has proven safe and highly effective. Progress in reducing global infections and deaths has been significant but requires an ongoing commitment. Eradication is theoretically possible but has proven elusive due to several factors, including natural and man-made disasters, which disrupt immunization programs, and more recently by elective vaccine avoidance.

cause an acute measles inclusion body encephalitis that is believed to be caused by persistent viral replication in the brain tissue of patients who are unable to mount an adequate immune response because of deficient cellular immunity.[11] The name derives from histologic evidence of viral persistence, which is seen by intracytoplasmic and intranuclear inclusions caused by nucleocapsids.

CNS infections can also trigger an immune response. In acute demyelinating encephalitis, an aberrant host response to myelin basic protein is thought to lead to brain inflammation and perivenous demyelination. In subacute sclerosing panencephalitis, patients are infected with mutated forms of the measles virus. Mutations in the M (matrix) gene may allow for long-term escape from host neutralizing antibody, and an altered F (fusion) gene leads to expression of an F protein with "hyperfusogenicity," which in turn allows for highly efficient cell-to-cell spread in neuronal tissues. Intranuclear inclusion bodies are seen in the neurons and glial cells of the white matter and neurons of the brainstem. An exaggerated host mononuclear inflammatory response occurs, with a vigorous leptomeningeal and parenchymal perivascular inflammation, which may be compounded by a degree of autoimmunity due to cross-reactivity between viral and myelin antigens. Early demyelination is followed by late stage cortical atrophy.

CLINICAL MANIFESTATIONS

Measles should be suspected in the presence of fever and a maculopapular (nonvesicular) rash. Measles has a 7- to 21-day incubation period, with onset of fever and malaise (prodrome), as well as the more specific combination of a "croupy or brassy" cough, coryza, conjunctivitis, and photophobia beginning about 10 days after exposure (Fig. 338-1). Koplik spots (Fig. 338-2),[12] which are raised bluish-white papules inside both cheeks, may appear at this time; though pathognomonic, they are often missed or misdiagnosed as thrush, and they fade as the rash emerges. The classic erythematous blanching maculopapular rash begins on the face, spreads down the body, and becomes confluent and darker in color over days (Fig. 338-3A). The rash is more subtle in dark-skinned patients (Fig. 338-3B), in whom the diagnosis may be delayed. In malnourished and immunosuppressed individuals, a prolonged desquamating dermatitis is commonly seen (Fig. 338-3C). Body temperature is high, 39° to 40.5° C, beginning with the prodrome and continuing at least 4 days into the rash. Patients are contagious to others from 4 days prior until 4 days after onset of the rash. As the rash darkens and fades, the skin will often flake and peel. In individuals with incomplete postimmunization protection, clinical symptoms may be milder, with less fever and catarrh, a later onset (12 to 16 days), and markedly reduced infectivity.[13]

Complications

Approximately one fourth of the reported measles cases identified in the United States from 2002 to 2016 resulted in hospitalization. Of these 1018 patients, reported complications included dehydration (16%), hyponatremia (14%), diarrhea (10%), thrombocytopenia (10%), pancytopenia (3%), conjunctivitis (9%), septicemia (8%), bacterial pneumonia (8%), bronchitis (4%), pleurisy (4%), and viral pneumonia (1%). One of the most specific though rare complications was encephalitis (2%).[14] By comparison, complications seen in 307 children admitted to a children's hospital in Islamabad, Pakistan from 2013 through 2017 included pneumonia (63%) and encephalitis (9%).[15]

Central Nervous System Involvement

Involvement of the CNS leads to several of the most serious complications of measles infection, with high rates of morbidity and mortality.

Acute and Subacute Encephalitis

An acute encephalitis may occur in the midst of clinical illness in 2 to 3% of infections and may explain why 5 to 10% of survivors have moderate to severe sensorineural hearing loss. A much rarer (0.1%) early, postinfectious, demyelinating encephalomyelitis occurs days after the apparent resolution of a primary infection. This syndrome, which is manifested by seizures and altered mental status, is fatal in 20% of cases, and more than one third of survivors have permanent neurologic sequelae.

Measles Inclusion Body Encephalitis

A measles inclusion body encephalitis may occur in immunosuppressed individuals, usually 1 to 6 months postinfection. Patients usually present with refractory focal seizures and rapidly progressive neurologic decline.[16]

Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis is a relentlessly progressive and uniformly fatal degenerative brain disorder that develops 7 to 10 years after measles infection. It occurs in 4 to 11 of every 100,000 survivors of measles infection, but rates are several times higher in resource-restrained countries, as well when measles infection occurs at a young age.[17,18] Patients typically present with cognitive and behavioral changes. A chorioretinitis may precede the more obvious CNS involvement. The result is an initial cognitive decline, followed by loss of motor skills, visual loss, and verbal difficulties, eventually leading to a persistent vegetative state and ultimately death.

DIAGNOSIS

Many diseases in children and adults have morbilliform rashes and systemic findings, including the multiorgan systemic inflammatory syndromes associated with the SARS-CoV-2 pandemic (Chapter 336), which frequently

FIGURE 338-2. Typical Koplik spots.

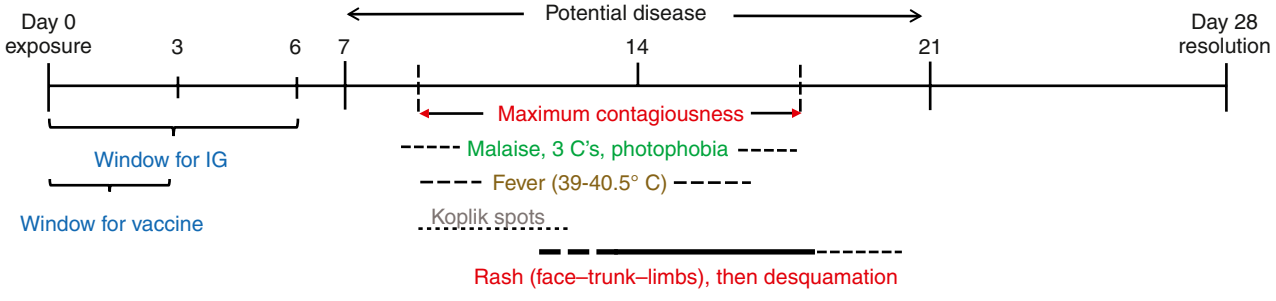

FIGURE 338-1. Clinical progression of measles. 3 Cs = cough, coryza, conjunctivitis; IG = immunoglobulin.

FIGURE 338-3. **The variable rash of measles. A,** Classic erythematous rash, conjunctivitis, and coryza. **B,** Rash is difficult to perceive on dark skin, but patient has typical conjunctivitis and coryza. **C,** Prolonged desquamating dermatitis in a malnourished child with measles.

manifest with nonspecific maculopapular or morbilliform rashes during acute illness in older adults. However, the recognition of the unique pediatric multisystem inflammatory syndrome in children (MIS-C) further complicates the diagnostic challenges presented by morbilliform rashes in the younger child, in whom a wide variety of patterns of erythematous rashes are manifest in about 50% of patients up to a month or longer after COVID-19 infection. Clinicians must use experience and judgment to decide if there is substantial risk that a patient's illness may be measles and represent the index case of a potential outbreak (Table 338-1), which may require immediate intervention.

Suspected measles infection must be confirmed by reverse transcription–polymerase chain reaction (RT-PCR) testing of samples obtained from sites of shedding, including the nasopharynx, oropharynx, conjunctiva, and even urine; or confirmatory serology. Unvaccinated infected individuals may develop an elevated measles-specific immunoglobulin M (IgM) antibody as soon as the first day of rash, whereas acute and convalescent serologies can detect a four-fold or greater rise in measles-specific antibody. Patients may have marked leukopenia and lymphopenia.

Virus recovery by PCR or culture also allows epidemiologists to genotype the isolate and to help control outbreaks. Clinicians should confer with regional or national public health experts if a case of measles is confirmed.

Neurologic Syndromes

Acute measles encephalitis is associated with a mild lymphocytic pleocytosis in the cerebrospinal fluid. Measles inclusion body encephalitis is usually diagnosed by brain biopsy. The diagnosis of subacute sclerosing panencephalitis can be confirmed by a classic pattern of periodic stereotypic sharp-slow wave discharges on electroencephalography, plus finding high titers of measles IgM and IgG in cerebrospinal fluid and serum.

TREATMENT

Treatment is supportive, with control of fever, hydration, nutrition, and observation for the serious complications of pneumonia and encephalitis (see Prognosis). Clinicians who rarely see measles may be alarmed by the prolonged high fever and malaise. Hospital admission for hydration or other concerns must be weighed against the challenge of infection control.

Vitamin A supplementation is recommended to reduce overall mortality and potentially reduce the risk for xerophthalmia, corneal scarring, and blindness, as well as the debilitating prolonged diarrhea of measles, especially in populations with vitamin A deficiency or malnutrition.[A1] Dosing is 50,000 units for infants younger than 6 months, 100,000 units for children aged 6 to 11 months, and 200,000 units for patients older than 12 months on both days 1 and 2 of presentation. An additional dose can be given 2 to 6 weeks later to patients with ophthalmic findings of vitamin A deficiency.

There are no proven therapies for any of the CNS complications of measles virus infection. Isoprinosine, ribavirin, and interferon-alpha have all been tried, with limited observational evidence that they may slow these progressive diseases. Experimental therapies include competitive antagonists and neutralizing antibodies, which may block the fusogenic properties of the mutated viral F protein in measles inclusion body encephalitis and subacute sclerosing panencephalitis.

PREVENTION

Immunization with Live Virus Vaccines

Immunization with live-attenuated measles virus vaccine, often as MMR and sometimes with varicella (MMRV), stimulates long-acting antibodies and cellular immunity.[A2] Immunization strategies are designed both to protect the individual and to ensure that least 89 to 94% of a population is protected, a level required to diminish measles propagation within the population, termed "herd immunity."

Two immunizations should be delivered, at least 1 month apart, when the protective yet also vaccine-inhibitory effects of passively transferred maternal antibody diminish (Chapter 15). The first dose is routinely administered at 9 to 12 months of age and can be given as early as 6 months if the infant is born during an outbreak or high-risk situation or is traveling to such a region. If it is given before 9 months of age, a third dose is needed to ensure that two are given after the loss of maternal antibody. The second dose can be given from 1 month to years later, often at entry to formal schooling.

As the world's population shifts to relying on vaccine immunity, further doses during adulthood may be required because the estimated waning of immunity is about 0.9%/year.[19] For example, only 82% of recent U.S. military recruits had detectable measles titers, lower than the level desired for herd immunity, and recruits older than 30 years had even lower rates, possibly suggesting waning titers. A recent systematic review found evidence of high rates of seroconversion (96 to 100%) and no additional safety concerns in recipients greater than 7 years of age.[20]

Enthusiasm has been growing for a dried measles and rubella live vaccine combination that can be delivered by a cutaneous patch microneedle intradermal delivery system.[21] This approach could overcome the current logistic challenges required by the current vaccines' requirements for strict temperature storage and need for injection.

Vaccine Safety

Measles vaccine is highly safe, with minimal side effects. Common reactions include fever 6 to 12 days after immunization in less than 15% of cases and

TABLE 338-1 DIAGNOSING MEASLES

CLINICAL PRINCIPLE	QUESTIONS TO ASK
Measles is acquired only from a person with measles	Travel to endemic areas or regions with outbreaks Warnings from health department/CDC of local measles Suspicious ill contacts with risk factors
The individual must be susceptible	Natural immunity (born before 1957, history of infection) Is the patient inadequately immunized or immunosuppressed
Most patients are ill-appearing	Ill enough to consider "admission" to a hospital (a rash in an otherwise well individual is rarely measles)
There is a predictable evolution of systemic findings	Croupy cough, coryza, and conjunctivitis (3 Cs) Relentless high fever for several days Did Koplik spots precede the rash (often unrecognized)
The rash is impressive, with a few exceptions	Previously healthy patient with lighter skin color—is there a distinct rash (see Fig. 338-3A) Hard to distinguish due to darker skin color in this previously healthy infant (see Fig. 338-3B) "Head-trunk-limb" progression, increasing confluence Is patient malnourished/immunosuppressed (rash can be absent/atypical; see Fig. 338-3C)
Other diagnoses are much more common	Enterovirus (Chapter 349), parvovirus (Chapter 342), roseola (Chapter 406), rubella (Chapter 339), EBV (Chapter 348), streptococcal/staphylococcal (Chapters 267 and 268), primary COVID-19 or MIS-C after COVID-19 (Chapters 335, 336, and 337), toxin Risk for rickettsia illnesses (Chapter 302) in region, outdoor exposure Kawasaki disease (Chapter 249), other vasculitis, or immunologic disease Risks for drug toxicity—new medications (Chapter 234)
The experience of the examining clinicians is critical	Clinicians from the 1960s-1980s, or with global experience Team consensus. This will be a public health emergency! Ability to confirm rapidly by acute IgM serology or PCR

CDC = Centers for Disease Control and Prevention; COVID-19 = coronavirus disease 2019; EBV = Epstein-Barr virus; IgM = immunoglobulin M; MIS-C = multisystem inflammatory syndrome of childhood; PCR = polymerase chain reaction.

transient rashes or lymphadenopathy in less than 5% of children and 20% of adults. The rubella component of the MMR may trigger transient arthralgia or arthritis in postpubertal girls. Febrile seizures occur in 1 in 1100 to 1400 infants at 5 to 12 days after immunization, and transient thrombocytopenia may occur in 1 in 22,000 to 40,000 individuals at 2 to 3 weeks postimmunization. Allergic reactions and anaphylaxis are rare. No evidence supports any causal relationship between receipt of measles vaccine and autism-spectrum disorders or autoimmune disorders, including Guillain-Barré syndrome, inflammatory bowel disease, and type 1 diabetes.

Immunization is encouraged for individuals with early-stage human immunodeficiency virus (HIV) who are successfully managed with antiviral therapy, and reimmunization should be considered for children who have immune reconstitution later in life. MMR vaccines are avoided in pregnant women or those who may become pregnant in the subsequent 28 days, primarily to avoid exposure to the rubella component, although vaccine-associated problems for any component are extraordinarily rare. MMR or MMRV vaccine should be avoided in patients with primary or acquired immunodeficiency (Chapters 231 and 353), including late-stage HIV or ongoing systemic immunosuppressive therapy, and in patients who have recently received antibody-containing blood products (immunoglobulin or whole blood), which might inhibit the vaccines. Measles and other immunizations should be planned around the timing of induction and recovery from immunosuppression for the growing group of patients who receive targeted immunotherapies.

Isolation of Suspected Infected Individuals and Postexposure Prophylaxis

Immediate isolation of suspected cases and quarantine of any contacts without presumptive immunity are standard practices. Hospitalized patients are ideally managed in negative-air-pressure isolation rooms using airborne precautions.

If a risk for exposure has been identified early, contacts can be screened for natural immunity or adequate immunization; if indicated, a dose of measles vaccine can be delivered within 72 hours of exposure. Passive immunoprophylaxis with human immunoglobulin preparations can achieve protective levels of antimeasles antibody in patients who were exposed between 3 and 6 days earlier, are pregnant, have late-stage HIV infection, or have other contraindications to vaccine.

Vaccine Hesitancy

Voluntary avoidance or delay of measles immunization, termed vaccine hesitancy, is a growing problem. In the resurgence of measles in the United States in 2019, 75% of cases were in small communities with high densities of underimmunized children, who were exposed to international travelers who unknowingly returned with measles infection. In the United States, the vaccine rate is about 95%, but it varies by locale. Counties with lower vaccination rates have higher rates of measles, with just 17 counties accounting for more than 50% of U.S. confirmed cases.[22] Parents under age 30 and parents with a single child are more likely to avoid vaccination. Both Internet and social media sources of information are significantly associated with vaccine hesitancy and negatively associated with correct knowledge about measles infection and vaccination.[23] The global challenge remains to eliminate barriers to timely measles immunization for all populations.

Global Strategies

In light of the failure to reach 2020 goals for eliminating measles in 5 of 6 global regions, the current global strategic plan steers away from specific numerical goals, and identifies several of the greatest current challenges, including health system weaknesses that result in immunity gaps in young infants and older age groups, inadequate mechanisms for "catch-up", inadequate surveillance, lack of resources for outbreak control, increasing vaccine hesitancy, and the recent reduction in supplemental immunization activities due to the COVID-19 pandemic.[24] Strategic planning includes tailoring programs to local challenges, implementing comprehensive and sustainable life-course immunization strategies with "catch-up" vaccination programs, using cross-border information sharing and collaboration for surveillance, and pursuit of innovative technologies that may simplify diagnostic tests and vaccines.

PROGNOSIS

Fatality rates are 2 to 3 per 1000, mostly in infants or adults older than 30 years. Among the 1018 patients admitted to hospitals in the United States from 2002 to 2016, a total of 34 deaths were noted (3.4% mortality). Fatality rates rise to 1 to 15% in populations with malnutrition and vitamin A deficiency. In the report of complications in children hospitalized in Islamabad the overall mortality was 17%, and was significantly associated with an underweight status with signs of nutritionally related growth retardation.

Patients who develop neurologic complications have a poor prognosis. Acute measles encephalitis is associated with permanent sensorineural hearing loss. Subacute demyelinating encephalitis is fatal in 20% of cases, and more than one third of survivors have permanent neurologic sequelae. Measles inclusion body encephalitis is rapidly progressive and typically fatal. Subacute sclerosing panencephalitis invariably leads to a vegetative state and death.

RUBELLA (GERMAN MEASLES)

GREGORY A. POLAND, INNA G. OVSYANNIKOVA, AND RICHARD B. KENNEDY

DEFINITION

Although most cases of rubella infection lead to a mild viral illness, significant morbidity occurs when rubella virus infects the fetus, particularly during the first trimester of pregnancy, when it causes miscarriage and the congenital rubella syndrome in up to 90% of cases.[1] Humans are the only known host, so this disease is eradicable.

The Pathogen

Rubella is a single-stranded, positive-sense RNA virus that is a member of the *Togaviridae* family, in the *Rubivirus* genus. The virus has a diameter of about 60 nm and includes a core protein and two envelope proteins.

EPIDEMIOLOGY

Rubella virus is spread person to person via the respiratory route, with lifelong immunity after infection. Prior to the availability of live attenuated rubella vaccine, rubella infection was nearly ubiquitous among children, occurring in the spring season and in large epidemics every 3 to 8 years. In the prevaccine era, up to 4 infants out of every 1000 live births worldwide were born with congenital rubella syndrome, and the incidence of congenital rubella syndrome was between 0.1 to 0.2 per 1000 live births during endemic phases and 0.8–4.0 during epidemics. With widespread use of the vaccine, the number of cases has been dramatically reduced.[2] Rubella was eliminated in the United States in 2004 and in the Americas since 2015. In the United States, fewer than 10 cases occur per year among individuals infected outside of the country. Unfortunately, global plans to eliminate rubella in 5 of 6 World Health Organization regions by 2020 failed,[3] and about 50% of babies worldwide do not have access to rubella-containing vaccines. Rubella outbreaks have continued to occur related to partial vaccination strategies, lack of political commitment, disruption due to war and conflict, and the costs of elimination programs. Herd immunity thresholds, which have varied by geographic region, have generally ranged from 70 to 90%, given a basic reproductive rate that is estimated to be 3 to 8 in Western settings but as high as 12 in crowded developing settings.

PATHOBIOLOGY

Rubella virus is a respiratory pathogen that enters through the oral and/or nasal mucosa, where it initially infects the nasopharyngeal epithelial cells and spreads to regional lymph nodes. The virus then enters the bloodstream, thereby causing viremia approximately 1 week into the incubation period. In healthy children and adults, infection can involve multiple organ systems, likely due to the broad range of permissive cells with low titer viral replication and little to no cytopathic effect.[4] In pregnant women, placental infection can provide access to fetal tissues, where widespread and persistent infection can occur. Fetal infection causes widespread cell death, disruption of cell division, and damaged, delayed, and/or disrupted organogenesis, thereby leading to developmental abnormalities in up to 90% of infected fetuses. The virus can be shed from infected newborns for up to 1 year following birth, and this shedding represents an infection risk for immunologically naïve contacts.

Rubella virus is present in the skin, where direct infection or the resulting antiviral immune response may contribute to the development of the rash. Chronic joint disease is related to persistent viral infection and the presence of immune complexes in synovial fluid. In the pancreas and thyroid, rubella infection and the autoimmune response can cause endocrine dysfunction. Viral infection of the brain in congenital rubella syndrome is believed to be the cause of the neurologic sequelae of encephalitis, progressive rubella panencephalitis, and other neurologic sequelae of congenital infection.

CLINICAL MANIFESTATIONS

Acquired rubella is often a mild, self-limiting, and benign viral disease. After an incubation period of 14 to 21 days, a fever is usually followed by a maculopapular erythematous rash (Fig. 339-1) within 2 days.[5,6] The virus can be transmitted to others up to 7 days after the rash appears. During this time, patients tend to experience relatively mild symptoms, such as low-grade fever, malaise, mild conjunctivitis, sore throat, ear infection, and upper respiratory symptoms. Posterior auricular lymphadenopathy is very common.[7] Acquired rubella is usually self-limited, and the ***vast*** majority of patients fully recover. However, transient arthritis, arthralgia, and joint pain are reported in up to 70% of adults after rubella infection. Rare complications may include thrombocytopenia (in about 1 in 300 cases) and encephalitis (in about 1 in 6000 cases).

FIGURE 339-1. Rash of rubella on the skin of a child's back. The distribution is similar to that of measles, but the lesions are less intensely red. (From the Centers for Disease Control and Prevention Public Health Image Library, ID #: 712.)

The main public health concern posed by rubella is its teratogenicity. Infection during early pregnancy (8 to 10 weeks of gestation) may result in devastating consequences (e.g., fetal death, miscarriage, and fetal abnormalities), described as congenital rubella syndrome. The defects associated with congenital rubella syndrome in infants most frequently result in serious ocular (e.g., glaucoma, cataracts, retinitis, microphthalmia, chorioretinitis), hearing (e.g., cochlear deafness), brain (e.g., microcephaly, encephalitis), or cardiac disease (e.g., peripheral pulmonary artery stenosis, patent ductus arteriosus) (Table 339-1).[8]

DIAGNOSIS

Clinical specimens for the diagnosis of rubella infection in humans include blood, oral fluids, throat swabs, nasopharyngeal secretions, saliva, and urine. Amplification of rubella virus RNA from clinical specimens using the reverse transcription polymerase chain reaction (RT-PCR) method that has 100% sensitivity and 90% specificity[9] and is the preferred method for rapidly distinguishing rubella from measles (Chapter 338). The much more cumbersome alternative is to grow the virus in cultured African green monkey kidney cells.

For serologic diagnosis, a combination of laboratory methods can confirm recent rubella infection, congenital rubella infection, and congenital rubella syndrome. A four-fold increase in the level of rubella-specific IgG antibody titers between the acute and convalescent phase of illness is also used for serologic diagnosis of postnatal rubella infection. Detection of rubella virus-specific IgM antibodies can diagnose recent maternal and postnatal infection, and it is useful for the rubella and congenital rubella syndrome surveillance programs. In highly immunized populations, however, antibody-positive results are more likely to reflect prior immunization rather than recent primary infection.[10] Serum antibody levels between 10 IU/mL and 15 IU/mL indicate immunity to rubella; an antibody level of 15 IU/mL probably correlates with immune protection.

TREATMENT

Unfortunately, no rubella-specific treatments are useful for prophylactic, therapeutic, or curative purposes. Treatment is supportive and can include fluids, rest, and antipyretics for fever. For pregnant women who have been exposed to rubella, hyperimmune gamma globulin has been used but with only modest definitive evidence of benefit.[A1]

ABSTRACT

Rubella virus, which remains an important pathogen globally, is the causative agent of the disease often known as German measles. Acquired rubella infection is often typified by a rash with self-limiting and benign disease. However, infection during early pregnancy can result in devastating consequences, such as fetal abnormalities and fetal death, collectively known as congenital rubella syndrome. Nucleic acid amplification or serologic tests can diagnose rubella infection. Active immunization using live attenuated rubella virus vaccine, typically given as part of a childhood immunization schedule, prevents infection. For seronegative pregnant women, vaccine is administered postpartum, after which pregnancy should be delayed for 28 days. A strategic framework has been developed with the goal of eliminating rubella infection worldwide.

PREVENTION

Active immunization using live attenuated rubella virus vaccine[11] is 97% effective (range 94 to 100%) in preventing infection,[A2] including the congenital rubella syndrome. The vaccine is currently administered as a two-dose series in the United States as part of the measles-mumps-rubella (MMR-II) vaccine. Rubella vaccine is also licensed for use in children between 12 months and 12 years of age in combination with measles, mumps, and varicella (chickenpox) vaccines as the MMRV vaccine. MMR vaccines are very effective in preventing disease, although some studies have demonstrated suboptimal long-term immunity[12] and, uncommonly, seronegativity (<10 IU/mL antibody titer) in immunized persons.[13]

In newborns, passive rubella maternal antibodies disappear rapidly 2 months following birth, so the U.S. Centers for Disease Control and Prevention recommends children receive their first dose of the MMR vaccine between 12 and 15 months of age and the second dose later in childhood at age 4 to 6 years. Vaccination is recommended for high-risk groups including nonpregnant women of childbearing age, military recruits, college students, and health care workers. In the United States, a third dose of MMR vaccine may be recommended by state or local health authorities during measles or mumps outbreaks.

The estimated rate of loss of immunogenicity is about 1.2% per year.[14] Repeat vaccination is recommended in patients who are found to be seronegative. In cases of waning immunity, a repeat vaccination will raise the antibody response, but it generally wanes back to baseline. Although most vaccine-related side effects are mild (e.g., rash, fever, sore throat, lymphadenopathy, and headache), arthritis and arthralgia may occur, especially in adolescent rubella-seronegative women, but resolve over time. Rarely, the live attenuated vaccine can produce vaccine-related rubella in immunodeficient or even apparently immunocompetent patients.[15]

A third booster vaccination in seronegative and/or immunocompromised (e.g., after chemotherapy or bone marrow transplantation, or with congenital immune deficiency) children may induce immunity, but a live virus booster vaccination is not recommended for children with immunodeficiency or children who experienced thrombocytopenic purpura after MMR vaccination, due to the increased risks of adverse events after vaccination. Rubella vaccine also should not be given to individuals who had a severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose, or to patients with a known severe immunodeficiency.

Pregnancy should be avoided for 1 month after MMR vaccination, and the vaccine should be administered postpartum. MMR vaccine can be administered to breastfeeding mothers without any danger to their infant.

Worldwide eradication efforts continue.[16] However, issues with accessibility, public health infrastructure, and hesitancy have hampered such efforts.[17]

PROGNOSIS

Rubella is typically mild and transient in healthy children and adults, with nearly everyone recovering fully. Rubella encephalitis and postinfection panencephalitis, which resemble the subacute sclerosing panencephalitis that can follow measles infection (Chapter 338), occur at a rate of about 1 in 5000 infections and are associated with mortality rates as low as 0% and as high as 50%. Joint problems (e.g., polyarthralgia, polyarthritis), which are common in adults but not in children, are typically transient.[18] Treatment is limited to bed rest, adequate hydration, and mild pain relievers (e.g., acetaminophen or ibuprofen) for aches and fever.[19] The prognosis for congenital rubella syndrome is typically poor; although some specific symptoms can be treated, no cure exists.

340 MUMPS

JENNIFER B. ROSEN AND JANE R. ZUCKER

DEFINITION

Mumps is an acute viral infection characterized by inflammation of the parotid and other salivary glands. Prior to the introduction of vaccination in the United States, mumps was a common childhood illness. The incidence of mumps declined dramatically after the introduction of the vaccine, but mumps remains endemic. Cases and even outbreaks can occur in previously vaccinated children and adults.

The Pathogen

The mumps virus is an enveloped, negative-strand RNA virus belonging to the Paramyxoviridae family, genus *Rubulavirus*. Twelve mumps genotypes exist, denoted by letters A to N. The diversity of genotypes in circulation in the United States is low, with the majority being genotype G.[1]

EPIDEMIOLOGY

Humans are the only natural host of mumps virus. Mumps is highly contagious and spreads by close person-to-person contact via respiratory droplets. Transplacental transmission has rarely been reported. The incubation period between exposure to the onset of illness ranges from 12 to 25 days. Infected individuals are most likely to be contagious up to 2 days before through 5 days after the onset of symptoms, but individuals who have asymptomatic infections can also transmit the disease.

The introduction of mumps vaccine into the routine childhood immunization schedule for children ages 12 months and older in 1977 led to a dramatic decline in mumps disease in the United States, from over 150,000 cases of mumps in 1968 to about 3000 cases in 1985. In 1989, a second dose of measles-mumps-rubella (MMR) vaccine for children ages 4 to 6 years was added to the routine childhood immunization schedule and led to a further reduction, with an average of fewer than 300 reported cases annually through the early 2000s.[2,3]

However, mumps remains endemic in the United States, and multiple large outbreaks of mumps continue to occur, primarily involving fully vaccinated

PREVENTION

Active immunization using live attenuated rubella virus vaccine[11] is 97% effective (range 94 to 100%) in preventing infection,[A2] including the congenital rubella syndrome. The vaccine is currently administered as a two-dose series in the United States as part of the measles-mumps-rubella (MMR-II) vaccine. Rubella vaccine is also licensed for use in children between 12 months and 12 years of age in combination with measles, mumps, and varicella (chickenpox) vaccines as the MMRV vaccine. MMR vaccines are very effective in preventing disease, although some studies have demonstrated suboptimal long-term immunity[12] and, uncommonly, seronegativity (<10 IU/mL antibody titer) in immunized persons.[13]

In newborns, passive rubella maternal antibodies disappear rapidly 2 months following birth, so the U.S. Centers for Disease Control and Prevention recommends children receive their first dose of the MMR vaccine between 12 and 15 months of age and the second dose later in childhood at age 4 to 6 years. Vaccination is recommended for high-risk groups including nonpregnant women of childbearing age, military recruits, college students, and health care workers. In the United States, a third dose of MMR vaccine may be recommended by state or local health authorities during measles or mumps outbreaks.

The estimated rate of loss of immunogenicity is about 1.2% per year.[14] Repeat vaccination is recommended in patients who are found to be seronegative. In cases of waning immunity, a repeat vaccination will raise the antibody response, but it generally wanes back to baseline. Although most vaccine-related side effects are mild (e.g., rash, fever, sore throat, lymphadenopathy, and headache), arthritis and arthralgia may occur, especially in adolescent rubella-seronegative women, but resolve over time. Rarely, the live attenuated vaccine can produce vaccine-related rubella in immunodeficient or even apparently immunocompetent patients.[15]

A third booster vaccination in seronegative and/or immunocompromised (e.g., after chemotherapy or bone marrow transplantation, or with congenital immune deficiency) children may induce immunity, but a live virus booster vaccination is not recommended for children with immunodeficiency or children who experienced thrombocytopenic purpura after MMR vaccination, due to the increased risks of adverse events after vaccination. Rubella vaccine also should not be given to individuals who had a severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose, or to patients with a known severe immunodeficiency.

Pregnancy should be avoided for 1 month after MMR vaccination, and the vaccine should be administered postpartum. MMR vaccine can be administered to breastfeeding mothers without any danger to their infant.

Worldwide eradication efforts continue.[16] However, issues with accessibility, public health infrastructure, and hesitancy have hampered such efforts.[17]

PROGNOSIS

Rubella is typically mild and transient in healthy children and adults, with nearly everyone recovering fully. Rubella encephalitis and postinfection panencephalitis, which resemble the subacute sclerosing panencephalitis that can follow measles infection (Chapter 338), occur at a rate of about 1 in 5000 infections and are associated with mortality rates as low as 0% and as high as 50%. Joint problems (e.g., polyarthralgia, polyarthritis), which are common in adults but not in children, are typically transient.[18] Treatment is limited to bed rest, adequate hydration, and mild pain relievers (e.g., acetaminophen or ibuprofen) for aches and fever.[19] The prognosis for congenital rubella syndrome is typically poor; although some specific symptoms can be treated, no cure exists.

340 MUMPS

JENNIFER B. ROSEN AND JANE R. ZUCKER

DEFINITION

Mumps is an acute viral infection characterized by inflammation of the parotid and other salivary glands. Prior to the introduction of vaccination in the United States, mumps was a common childhood illness. The incidence of mumps declined dramatically after the introduction of the vaccine, but mumps remains endemic. Cases and even outbreaks can occur in previously vaccinated children and adults.

The Pathogen

The mumps virus is an enveloped, negative-strand RNA virus belonging to the Paramyxoviridae family, genus *Rubulavirus*. Twelve mumps genotypes exist, denoted by letters A to N. The diversity of genotypes in circulation in the United States is low, with the majority being genotype G.[1]

EPIDEMIOLOGY

Humans are the only natural host of mumps virus. Mumps is highly contagious and spreads by close person-to-person contact via respiratory droplets. Transplacental transmission has rarely been reported. The incubation period between exposure to the onset of illness ranges from 12 to 25 days. Infected individuals are most likely to be contagious up to 2 days before through 5 days after the onset of symptoms, but individuals who have asymptomatic infections can also transmit the disease.

The introduction of mumps vaccine into the routine childhood immunization schedule for children ages 12 months and older in 1977 led to a dramatic decline in mumps disease in the United States, from over 150,000 cases of mumps in 1968 to about 3000 cases in 1985. In 1989, a second dose of measles-mumps-rubella (MMR) vaccine for children ages 4 to 6 years was added to the routine childhood immunization schedule and led to a further reduction, with an average of fewer than 300 reported cases annually through the early 2000s.[2,3]

However, mumps remains endemic in the United States, and multiple large outbreaks of mumps continue to occur, primarily involving fully vaccinated

ABSTRACT

Mumps was a universal childhood illness in the United States prior to licensure of mumps vaccine in 1967. The national United States routine recommendation for two doses of MMR vaccine has greatly reduced the incidence of mumps, but outbreaks still occur in vaccinated populations. Mumps spreads person-to-person by respiratory droplets. Acute mumps is an infection characterized by inflammation of the parotid and other salivary glands, although 20 to 40% of infections are asymptomatic. Complications of mumps include orchitis in postpubertal males, mastitis and oophoritis in postpubertal females, pancreatitis, sensorineural hearing loss, myocarditis, nephritis, meningitis, and encephalitis. Complications are less common in previously vaccinated individuals. The differential diagnosis for parotitis is broad. Routine diagnostic testing includes a buccal swab for real-time polymerase chain reaction testing as well as serology for mumps immunoglobulin M. No specific treatment is available. Infection is usually self-limited, and treatment is supportive.

adolescents and young adults in densely populated settings. For example, a multistate mumps outbreak in 2006 involved more than 6500 people across multiple midwestern college campuses. During 2009 to 2010, large outbreaks occurred in Guam and in New York City, where more than 3500 individuals were infected in a close-knit religious community. From 2015 to 2019, multiple large outbreaks involved schools, universities, athletic teams, and religious groups. In a large outbreak in a close-knit community in Arkansas from 2016 to 2017, approximately 3000 individuals became infected.[4] Approximately 900 mumps cases were identified across 57 detention facilities in 19 states between 2018 and 2019.[5]

Mumps cases and outbreaks among fully vaccinated persons are likely due to a combination of factors.[6] One set of factors relates to the limits of vaccination. First is the potential for a mismatch between the MMR vaccine and the mumps strains in circulation. For example, sera from vaccinated persons against genotype A strain used in vaccines in the United States fully neutralizes the genotype G strain, which is the main genotype that has circulated in the United States since 2006, but geometric mean antibody titers are lower relative to titers against the vaccine strain. In addition, the mumps component of the MMR vaccine is less effective than the measles and rubella components, with an average initial seroconversion rate of 91% and a median two-dose effectiveness of 88%. Furthermore, immunity following mumps-containing vaccine wanes over time.[7,8] A second set of issues relates to infectivity. Persons may be contagious prior to the onset of symptoms or may be asymptomatic throughout their infections. Challenges with diagnostic testing, especially in vaccinated persons, may result in delayed or missed diagnoses, thereby allowing infected individuals to spread the disease. Finally, settings with intense exposures (e.g., colleges and universities, close-knit communities with large congregate gatherings) are conducive to outbreaks.

PATHOBIOLOGY

Mumps virus is presumed to replicate initially in the upper respiratory tract, followed by spread to lymph nodes and viremia. The virus most often then spreads to glandular tissues (e.g., parotid glands, testes, breasts, pancreas) and the central nervous system. Orchitis is caused by the replication of the virus in the seminiferous tubules. Mumps virus enters the central nervous system via venous vasculature of choroidal and ependymal epithelial cells, where it replicates and can enter brain parenchyma. Hearing loss is likely due to infection of the cochlea resulting from spread from cervical lymph nodes into perilymphatic fluid, although immune-mediated damage may also play a role.

Early in the course of infection, patients develop an initial immunoglobulin M (IgM) response (see Diagnosis section), which is followed by immunoglobulin G (IgG). Elevated IgG levels peak at 3 to 4 weeks after infection and can persist for decades.

CLINICAL MANIFESTATIONS

Mumps virus infection classically causes swelling of salivary glands (Fig. 340-1). The parotid gland is most commonly affected (parotitis), but submaxillary and sublingual gland swelling can occur as well. Parotitis can be unilateral or bilateral and usually resolves within 10 days. A prodrome of nonspecific symptoms, including low-grade fever, headache, malaise, myalgia, and anorexia, may precede the parotitis. Nonspecific upper respiratory symptoms may be the only symptom, and approximately 20 to 40% of infections are asymptomatic.

Complications of mumps include orchitis in postpubertal males, mastitis and oophoritis in postpubertal females, pancreatitis, sensorineural hearing loss, arthropathy, myocarditis, nephritis, meningitis, encephalitis, and autoimmune hemolytic anemia. Complications are less common in people who were previously vaccinated against mumps (Table 340-1).

Orchitis is reported in 15 to 35% of postpubertal males but rarely in younger males. Most cases are unilateral, but about 25% may be bilateral. It usually appears about a week after the parotitis but can also occur before or without parotitis. Symptoms can be prominent, with testicular swelling and pain; these symptoms usually resolve within about a week, but tenderness may persist for several weeks. Mumps orchitis can cause testicular atrophy, with a rare risk for subsequent infertility.

In up to 10% of unvaccinated persons with mumps, symptomatic aseptic meningitis can occur and be manifested as headache, neck stiffness, vomiting, and lethargy, usually about 4 to 5 days after onset of parotitis. About 50% of cases of documented mumps meningitis can occur without parotitis. Unilateral and sometimes bilateral hearing loss can occur. Rarely, patients can develop encephalitis with obtundation and seizures, aphasia, and paresis.

DIAGNOSIS

When viral parotitis is suspected, a history of mumps vaccination or detectable mumps IgG does not exclude the possibility of mumps infection in people with clinically compatible symptoms. Mumps-specific diagnostic testing includes collection of both a buccal swab to detect mumps virus by real-time polymerase chain reaction (PCR) testing as well as serology for mumps IgM. Mumps IgM is most likely to be detectable a few days after the onset of symptoms, but it may be transient or absent and often remains undetectable in previously vaccinated individuals, thereby highlighting the importance of PCR testing. PCR is most likely to detect mumps virus when collected soon after the onset of parotitis, but it may be positive for 8 to 10 days after the onset of symptoms. The yield of PCR testing may be increased by massaging of the parotid gland for 30 seconds prior to obtaining the swab. Mumps is a nationally notifiable disease in the United States, and all cases should be reported to the state or local health departments when the diagnosis is initially considered.

The differential diagnosis for parotitis (Chapter 393) is broad, given the various infectious (e.g., bacterial, viral) and noninfectious (e.g., sialolithiasis, ductal strictures, postradiation inflammation) causes of parotitis. Nonmumps causes of viral parotitis include influenza virus (Chapter 332), human parainfluenza viruses (Chapter 331), adenoviruses (Chapter 333), Epstein-Barr virus (Chapter 348), herpes simplex viruses (Chapter 345), enteroviruses (Chapter 349), parvovirus (Chapter 342), and cytomegalovirus (Chapter 347), among others.[9] However, mumps is the only known cause of epidemic parotitis, thereby making a mumps diagnosis more likely during an outbreak.

In suspected mumps meningitis or encephalitis, cerebrospinal fluid (CSF) examination usually shows about 400 to 500 cells/μL, usually monocellular cells but sometimes polymorphonuclear cells early in the course. The CSF

National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention. Last reviewed June 30, 2021. https://www.cdc.gov/vaccines/pubs/surv-manual/chpt09-mumps.html. Accessed January 4, 2022.

protein may be mildly elevated, and the glucose level is usually normal but can be low. PCR testing may document mumps virus.

TREATMENT

No specific treatment is available. Infection is usually self-limited, and treatment is supportive based on symptoms (e.g., analgesics, cold compresses, scrotal support for orchitis).

PREVENTION

Vaccination is the most important way to prevent mumps infection. The recommendation (Chapter 15) is two doses of MMR vaccine for children, one at 12 to 15 months and one at 4 to 6 years of age. Adults ages 18 years and older who have not been previously vaccinated and are at high risk for exposure to mumps, including students in post-high school educational settings, health care personnel, and international travelers, should receive two doses of MMR; one dose is recommended for other unvaccinated adults.[10,11]

Presumptive evidence of immunity to mumps includes any one of the following four criteria: documentation of immunization, with the number of doses dependent on age and setting; laboratory evidence of immunity (i.e., detection of mumps IgG); laboratory confirmation of disease (e.g., detection of mumps virus by PCR or mumps IgM by serology); or birth before 1957. Persons who have presumptive evidence of immunity to mumps are less likely to become infected with mumps virus relative to persons without it; however, such evidence should not be used to exclude a diagnosis of mumps. Requirements for documentation of mumps-containing vaccine or laboratory evidence of immunity to mumps are required for health care workers in several states and for children attending childcare and grades kindergarten through 12 in nearly all states.[12,13]

Contraindications to MMR vaccine include a history of severe allergic reaction (e.g., anaphylaxis) to a prior dose of MMR or to any MMR vaccine component, pregnancy, immunosuppression, and congenital or hereditary immunodeficiency in a first-degree relative unless the immunocompetence of the vaccine recipient has been verified.[14] Precautions to MMR vaccine include recent (≤11 months) receipt of an antibody-containing blood product, moderate or severe illness with or without fever, and history of thrombocytopenia or thrombocytopenic purpura. If tuberculosis testing needs to be performed, it should be done either any time before, simultaneously with, or at least 4 to 6 weeks after administration of MMR vaccine. Personal or family history of seizures of any etiology is a precaution to MMR-varicella (MMRV) vaccine because of an increased risk of febrile seizures seen in 12- to 23-month-olds; however, MMR and single antigen varicella vaccine may be given, preferably at the same visit. If not, then the two live virus vaccines, MMR and single antigen varicella, should be given at least 4 weeks apart.

Individuals who have been exposed to mumps virus and who lack presumptive evidence of immunity to mumps should be brought up to date with MMR vaccination to protect them from future exposures. However, vaccination after exposure will not prevent infection from an exposure that has already occurred, and no postexposure prophylaxis exists for individuals who are exposed to mumps virus. Individuals who have been exposed, especially those who lack presumptive evidence of immunity to mumps prior to exposure, are at risk for developing infection throughout the 12- to 25-day incubation period and should monitor for symptoms. Consultation with the local public health department is recommended to determine the need for quarantine during this period.

Given repeated outbreaks among individuals who have received two doses of MMR vaccine in settings with intense, prolonged close contact (e.g., colleges, universities), a third dose of mumps-containing vaccine is recommended for persons who are identified by public health authorities as part of a group at increased risk for mumps due to an outbreak.[15] A third dose in this setting does not serve as postexposure prophylaxis to prevent infection following an exposure that already occurred, but rather aims to reduce infection and complications among people who are at risk for ongoing exposures. Data on duration of protection following a third dose of mumps-containing vaccine are limited and, at this time, use of a third dose is not recommended for routine use in the general population.

Patients who have mumps require at least 5 days of both standard precautions and droplet precautions after the onset of parotitis. Outpatients should wear a mask and be isolated from other potentially susceptible persons. Hospitalized patients require a private room, masking if transported elsewhere in the hospital, and masking for all caregivers.

PROGNOSIS

Most people with mumps infection recover fully. Bilateral mumps orchitis can lead to a temporary reduction in fertility or even transient sterility, but the risk of permanent infertility, though uncertain, appears to be rare. Mumps meningitis is usually self-limited. Hearing loss is usually transient but rarely can be permanent. Death due to mumps is exceedingly rare, with most fatalities due to mumps encephalitis.

341 POLYOMAVIRUSES

HANS H. HIRSCH

HUMAN POLYOMAVIRUS

DEFINITION

Human polyomaviruses comprise at least 14 species, denoted human polyomavirus 1 to 14,[1] and five of these are associated with human diseases (Table 341-1). Of the types of polyomaviruses that infect humans, the principal causes of human disease are BK polyomavirus, JC polyomavirus, Merkel cell polyomavirus, human polyomavirus 7, and *Trichodysplasia spinulosa* polyomavirus.

The Pathogen

Polyomaviruses are nonenveloped virions that remain infectious for prolonged periods of time in the environment and partly resist alcoholic disinfectants. The small, circular, double-stranded DNA genome of approximately 5000 base pairs encodes for 5 to 6 major viral proteins that cannot be targeted by existing antiviral drugs. Polyomavirus genomes persist in the infected host cell nucleus as extrachromosomal DNA and are highly dependent on host cell proteins such as histones, transcription factors, and RNA- and DNA-polymerases.

EPIDEMIOLOGY

Seroprevalence studies of antibodies against the different human polyomavirus Vp1 capsid proteins indicate different exposure rates ranging from 10% for polyomavirus 9 to above 90% for BK polyomavirus (human polyomavirus 1) and human polyomavirus 10. Primary infections commonly occur independently from one another during childhood and adolescence, with smaller increases in seroconversion until the seventh decade of life. The route of transmission likely involves the respiratory, oropharyngeal, or gastrointestinal tract after direct contact or environmental exposure. There is little if any cross-neutralizing immunity against other human polyomavirus species. Ultimately, the average adult will be infected with 6 to 8 different human polyomaviruses.

PATHOBIOLOGY

The early viral gene region encodes regulatory proteins called large and small tumor antigens that interfere with the functions of pRb-retinoblastoma and the p53-protein, override the cell's control of division, and shift the host cells into S-phase to provide abundant enzymes and building blocks for efficient polyomavirus replication. The resulting hyperproliferative, transformed phenotype inactivates DNA-repair and apoptosis. Human polyomavirus-specific immunity relies upon neutralizing and opsonizing antibodies directed against receptor-binding and other domains on the viral capsid Vp1, thereby interfering with new rounds of infection and clearing circulating viral progeny and debris. Virus-specific CD4 helper and cytotoxic CD8 T cells aid in the clearance of virus-replicating cells. In immunocompetent individuals, these responses are sufficient to minimize local replication and to prevent polyomavirus diseases.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

No specific symptoms or signs have been linked to primary human polyomavirus infection in the general population, presumably because of subclinical

protein may be mildly elevated, and the glucose level is usually normal but can be low. PCR testing may document mumps virus.

TREATMENT

No specific treatment is available. Infection is usually self-limited, and treatment is supportive based on symptoms (e.g., analgesics, cold compresses, scrotal support for orchitis).

PREVENTION

Vaccination is the most important way to prevent mumps infection. The recommendation (Chapter 15) is two doses of MMR vaccine for children, one at 12 to 15 months and one at 4 to 6 years of age. Adults ages 18 years and older who have not been previously vaccinated and are at high risk for exposure to mumps, including students in post-high school educational settings, health care personnel, and international travelers, should receive two doses of MMR; one dose is recommended for other unvaccinated adults.[10,11]

Presumptive evidence of immunity to mumps includes any one of the following four criteria: documentation of immunization, with the number of doses dependent on age and setting; laboratory evidence of immunity (i.e., detection of mumps IgG); laboratory confirmation of disease (e.g., detection of mumps virus by PCR or mumps IgM by serology); or birth before 1957. Persons who have presumptive evidence of immunity to mumps are less likely to become infected with mumps virus relative to persons without it; however, such evidence should not be used to exclude a diagnosis of mumps. Requirements for documentation of mumps-containing vaccine or laboratory evidence of immunity to mumps are required for health care workers in several states and for children attending childcare and grades kindergarten through 12 in nearly all states.[12,13]

Contraindications to MMR vaccine include a history of severe allergic reaction (e.g., anaphylaxis) to a prior dose of MMR or to any MMR vaccine component, pregnancy, immunosuppression, and congenital or hereditary immunodeficiency in a first-degree relative unless the immunocompetence of the vaccine recipient has been verified.[14] Precautions to MMR vaccine include recent (≤11 months) receipt of an antibody-containing blood product, moderate or severe illness with or without fever, and history of thrombocytopenia or thrombocytopenic purpura. If tuberculosis testing needs to be performed, it should be done either any time before, simultaneously with, or at least 4 to 6 weeks after administration of MMR vaccine. Personal or family history of seizures of any etiology is a precaution to MMR-varicella (MMRV) vaccine because of an increased risk of febrile seizures seen in 12- to 23-month-olds; however, MMR and single antigen varicella vaccine may be given, preferably at the same visit. If not, then the two live virus vaccines, MMR and single antigen varicella, should be given at least 4 weeks apart.

Individuals who have been exposed to mumps virus and who lack presumptive evidence of immunity to mumps should be brought up to date with MMR vaccination to protect them from future exposures. However, vaccination after exposure will not prevent infection from an exposure that has already occurred, and no postexposure prophylaxis exists for individuals who are exposed to mumps virus. Individuals who have been exposed, especially those who lack presumptive evidence of immunity to mumps prior to exposure, are at risk for developing infection throughout the 12- to 25-day incubation period and should monitor for symptoms. Consultation with the local public health department is recommended to determine the need for quarantine during this period.

Given repeated outbreaks among individuals who have received two doses of MMR vaccine in settings with intense, prolonged close contact (e.g., colleges, universities), a third dose of mumps-containing vaccine is recommended for persons who are identified by public health authorities as part of a group at increased risk for mumps due to an outbreak.[15] A third dose in this setting does not serve as postexposure prophylaxis to prevent infection following an exposure that already occurred, but rather aims to reduce infection and complications among people who are at risk for ongoing exposures. Data on duration of protection following a third dose of mumps-containing vaccine are limited and, at this time, use of a third dose is not recommended for routine use in the general population.

Patients who have mumps require at least 5 days of both standard precautions and droplet precautions after the onset of parotitis. Outpatients should wear a mask and be isolated from other potentially susceptible persons. Hospitalized patients require a private room, masking if transported elsewhere in the hospital, and masking for all caregivers.

PROGNOSIS

Most people with mumps infection recover fully. Bilateral mumps orchitis can lead to a temporary reduction in fertility or even transient sterility, but the risk of permanent infertility, though uncertain, appears to be rare. Mumps meningitis is usually self-limited. Hearing loss is usually transient but rarely can be permanent. Death due to mumps is exceedingly rare, with most fatalities due to mumps encephalitis.

341 POLYOMAVIRUSES

HANS H. HIRSCH

HUMAN POLYOMAVIRUS

DEFINITION

Human polyomaviruses comprise at least 14 species, denoted human polyomavirus 1 to 14,[1] and five of these are associated with human diseases (Table 341-1). Of the types of polyomaviruses that infect humans, the principal causes of human disease are BK polyomavirus, JC polyomavirus, Merkel cell polyomavirus, human polyomavirus 7, and *Trichodysplasia spinulosa* polyomavirus.

The Pathogen

Polyomaviruses are nonenveloped virions that remain infectious for prolonged periods of time in the environment and partly resist alcoholic disinfectants. The small, circular, double-stranded DNA genome of approximately 5000 base pairs encodes for 5 to 6 major viral proteins that cannot be targeted by existing antiviral drugs. Polyomavirus genomes persist in the infected host cell nucleus as extrachromosomal DNA and are highly dependent on host cell proteins such as histones, transcription factors, and RNA- and DNA-polymerases.

EPIDEMIOLOGY

Seroprevalence studies of antibodies against the different human polyomavirus Vp1 capsid proteins indicate different exposure rates ranging from 10% for polyomavirus 9 to above 90% for BK polyomavirus (human polyomavirus 1) and human polyomavirus 10. Primary infections commonly occur independently from one another during childhood and adolescence, with smaller increases in seroconversion until the seventh decade of life. The route of transmission likely involves the respiratory, oropharyngeal, or gastrointestinal tract after direct contact or environmental exposure. There is little if any cross-neutralizing immunity against other human polyomavirus species. Ultimately, the average adult will be infected with 6 to 8 different human polyomaviruses.

PATHOBIOLOGY

The early viral gene region encodes regulatory proteins called large and small tumor antigens that interfere with the functions of pRb-retinoblastoma and the p53-protein, override the cell's control of division, and shift the host cells into S-phase to provide abundant enzymes and building blocks for efficient polyomavirus replication. The resulting hyperproliferative, transformed phenotype inactivates DNA-repair and apoptosis. Human polyomavirus-specific immunity relies upon neutralizing and opsonizing antibodies directed against receptor-binding and other domains on the viral capsid Vp1, thereby interfering with new rounds of infection and clearing circulating viral progeny and debris. Virus-specific CD4 helper and cytotoxic CD8 T cells aid in the clearance of virus-replicating cells. In immunocompetent individuals, these responses are sufficient to minimize local replication and to prevent polyomavirus diseases.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

No specific symptoms or signs have been linked to primary human polyomavirus infection in the general population, presumably because of subclinical

ABSTRACT

Polyomaviruses comprise more than 100 species that have been detected in a variety of hosts, including birds, fish, and mammals. At least 14 have been detected in humans and are denoted human polyomaviruses 1 to 14.

Seroprevalence studies of antibodies against the different human polyomavirus Vp1 capsid proteins indicate exposure rates ranging from 10% for human polyomavirus 9 to above 90% for BK polyomavirus (human polyomavirus 1) and human polyomavirus 10. Human polyomavirus infections commonly occur independently from one another during childhood and adolescence, with little if any cross-neutralizing immunity against other human polyomavirus species. Smaller increases in seroconversion are observed until the seventh decade of life. The average adult individual is ultimately infected with 6 to 8 different human polyomaviruses. The route of transmission likely involves the respiratory, oropharyngeal, or gastrointestinal tract after direct contact or environmental exposure.

No specific symptoms or signs have been linked to primary human polyomavirus infections in the general population, presumably because of its subclinical or nonspecific manifestations. In immunocompromised patients, however, human polyomaviruses, especially BK polyomavirus, JC polyomavirus, and Merkel cell polyomavirus, can cause major diseases of the renourinary tract, the central nervous system, and the skin. The specific diagnosis depends on detecting the expression of viral proteins in the affected tissues of patients who have symptoms or signs that are consistent with underlying human polyomavirus. Because of viral persistence, detection of viral genomes by PCR is not sufficient to diagnose disease. Currently available antiviral agents have no proven benefit, so the main treatment is to improve virus-specific immune functions. Such approaches are often slow, limited, or simply not feasible because of the underlying condition that provides the environment for polyomavirus disease.

TABLE 341-1 HUMAN POLYOMAVIRUSES, THEIR DISEASE, AND POPULATION AT RISK

COMMON NAME	TAXONOMIC NAME	GENERAL TROPISM	SERO-PREVALENCE	SIGNATURE DISEASES (ORGAN)	PATHOGENIC PRINCIPLE	POPULATION AT HIGH RISK
BK polyomavirus (BKPyV)	HPyV1	Kidney, urinary tract	80-95%	Nephropathy (kidney)	Replicative—cytopathic necrosis, inflammatory	Kidney transplantation
				Hemorrhagic cystitis (bladder, ureters, renal pelvis)	Replicative—cytopathic, IRIS	Allogeneic hematopoietic cell transplantation
				Urothelial cancer (ureters, renal pelvis, metastasis)	Non-replicative transforming	Kidney transplantation (rarely other solid organ or hematopoietic cell transplantation)
JC polyomavirus (JCPyV)	HPyV2	Urinary tract, kidney, CNS	60-90%	Progressive multifocal leukoencephalopathy (cerebrum, cerebellum)	Replicative—cytopathic Replicative—cytopathic—inflammatory (progressive multifocal leukoencephalopathy, IRIS)	HIV/AIDS Multiple sclerosis (natalizumab therapy)
				Nephropathy (kidney)	Replicative—cytopathic inflammatory	Kidney transplantation
Merkel cell polyomavirus (MCPyV)	HPyV5	Skin	50-80%	Merkel cell carcinoma (skin, metastasis)		Immunocompromised patients, elderly, sun exposure, chronic hematologic malignancy, solid organ transplantation
Human polyomavirus	HPyV7	Skin	30-70%	Pruritic hyperproliferative keratinopathy (skin)		Immunocompromised patients (solid organ transplantation)
Trichodysplasia spinulosa polyomavirus (TSPyV)	HPyV8	Skin	70-90%	Trichodysplasia spinulosa (skin)		Immunocompromised patients (chronic lymphatic leukemia, solid organ transplantation)

AIDS = acquired immunodeficiency syndrome; CNS = central nervous system; HIV = human immunodeficiency virus; IRIS = immune reconstitution inflammatory syndrome.

or nonspecific manifestations. In immunocompromised patients, however, human polyomaviruses can cause major diseases of the renourinary tract, central nervous system, and skin.

BK POLYOMAVIRUS

BK polyomavirus is the main cause of nephropathy after kidney transplantation, of hemorrhagic cystitis after allogeneic hematopoietic cell transplantation, and of urothelial carcinoma (see Table 341-1). Other manifestations are rare, such as nephropathy of native kidneys, ureteritis-pyelitis, pneumonitis, meningoencephalitis, encephalopathy, and multiorgan failure. BK polyomavirus's four serotypes (I, II, III, IV) can be further divided into 12 subtypes based on their genomic sequences.[2] Seroepidemiologic evidence indicates that BK polyomavirus infects 95% of the general population during childhood, but antibody levels tend to decline during adult life. Following primary viremia, BK polyomavirus establishes a persistent infection in the renourinary tract, and about 10% of seropositive healthy persons have asymptomatic, low-level viruria (median 5000 copies/mL) but no detectable viremia.[3] Substantial weakening of the immune control by immunosuppressive drugs, chemotherapy, cortico-steroids, or lymphocyte-depleting agents typically results in high-level viruria (>10 million copies/mL) that remains clinically silent except in a subgroup of recipients of kidney transplant (Chapter 117) and allogeneic hematopoietic stem cell transplant (Chapter 163).

BK Polyomavirus–Associated Nephropathy

DEFINITION

In BK polyomavirus–associated nephropathy, the structure and function of nephrons is damaged by progressive viral replication, thereby resulting in denuded tubular basement membranes, interstitial inflammation, tubulitis, interstitial fibrosis, and tubular atrophy that cause progressive functional decline and end-stage renal failure.

EPIDEMIOLOGY

BK polyomavirus nephropathy almost exclusively affects recipients of kidney transplants and is rarely diagnosed in other immunocompromised populations despite similar or higher intensity of immunosuppression. Biopsy-proven disease develops in about 8% (range 1% to 15%) of patients in the first 2 years after kidney transplantation,[4,5] but the true rates are higher because focal early-stage involvement, especially in the medulla, is missed by needle biopsy. Given the approximately 75,000 kidney transplants annually in North America and Europe, about 7500 kidney patients per year are at risk for premature renal allograft failure and return to dialysis.

BK polyomavirus–DNAemia levels correlate with onset, extent, and resolution of proven BK polyomavirus–associated nephropathy[6] and then drop to undetectable levels with half-lives of less than 2 hours upon allograft nephrectomy. The risk of BK polyomavirus–DNAemia and nephropathy is higher with tacrolimus compared with cyclosporine immunosuppression, is lower for mTOR inhibitor combinations, and increases following treatment with high-dose corticosteroids for acute rejection (Chapter 117).

Recipient risk factors include male gender, older age, and low or undetectable levels of BK polyomavirus–specific antibodies, as well as lack of certain human leukocyte antigen (HLA)-types such as B51, B7, B8, and A24. Donor risk factors include pretransplant urinary shedding of BK polyomavirus, exposure to a BK polyomavirus subtype to which the recipient does not have detectable antibodies, and an increasing number of HLA-mismatches.

PATHOBIOLOGY

By transplanting the kidney, recipients are exposed to latent or replicating BK polyomavirus in the donor organ. Lack of sufficient BK polyomavirus–specific immunity leaves viral replication unchecked, with corresponding cytopathic changes of the renal tubular epithelial cells. Less frequently, the recipient's own virus gains access to the renal allograft by reflux from the bladder. Lytic release of intranuclear virions permits cell-to-cell spread inside the tubules and to the downstream transitional and urothelial cells, thereby further amplifying viral replication and leading to average viruria of 100 million copies/mL. Increasing cytopathic damage and necrosis induce prominent interstitial inflammation and tubulitis, which are followed by irreversible interstitial fibrosis and tubular atrophy.

CLINICAL MANIFESTATIONS

BK polyomavirus nephropathy is initially asymptomatic without affecting the function of the allograft. As damage to the allograft progresses, however, the serum creatinine concentration increases. High-level viruria develops in 20% to 40% of kidney transplant recipients, approximately 50% of whom develop BK polyomavirus–DNAemia after 0.5 to 2 months as a sign of viral replication in the allograft. Without effective interventions, increasing levels and durations of BK polyomavirus–DNAemia are associated with declining renal allograft function.

DIAGNOSIS

Differentiating acute rejection from viral nephritis is important because the treatments (increasing or reducing immunosuppression) are the opposite of each other. In kidney transplant patients with declining renal function, a biopsy of the renal allograft is commonly indicated to search for T-cell-mediated or antibody-mediated rejection, drug toxicity, and BK polyomavirus nephropathy (Chapter 117). The cytopathic and immunohistochemistry changes of BK polyomavirus nephropathy are characteristic (E-Fig. 341-1).[7] In unclear cases, other viral diseases presenting with intranuclear inclusions (e.g., adenovirus, herpes simplex, and cytomegalovirus) should be excluded.

In kidney transplant patients who present with baseline renal function and sustained or increasing BK polyomavirus–DNAemia, a biopsy is not indicated because allograft biopsy cannot exclude BK polyomavirus nephropathy. Criteria for a clinical diagnosis are: probable BK polyomavirus nephropathy, defined as sustained plasma BK polyomavirus loads of greater than 1000 copies/mL for more than 2 weeks, and presumptive BK polyomavirus nephropathy, defined as plasma BK polyomavirus loads above 10,000 copies/mL or the corresponding genome equivalent.

TREATMENT AND PREVENTION

The treatment of probable, presumptive, and biopsy-proven BK polyomavirus nephropathy consists of reducing immunosuppression.[8] The specific protocols for reducing immunosuppression vary and must be supervised by experts. In general, the options are to reduce the dose of tacrolimus or cyclosporine in one or two steps, targeting trough levels of less than 6 ng/mL and less than 125 ng/mL, respectively. The dose of the antiproliferative drug (e.g., mycophenolic acid or mycophenolate mofetil) is reduced by 50% and discontinued in one or two steps. Oral prednisone is typically tapered to 10 mg or less per day. Patients should have their serum creatinine concentrations measured at least weekly and their plasma viral loads measured at least bi-weekly. Cidofovir, leflunomide, fluoroquinolones, and intravenous immunoglobulin have been administered in addition, but their use is not supported by randomized trials.[9]

Pretransplant screening of donors and recipients for BK polyomavirus viruria or for specific antibody levels is currently not recommended because clinical studies have not assessed the risks and benefits of integrating this information into post-transplantation care. After transplantation, however, all kidney transplant recipients should be screened for BK polyomavirus–DNAemia monthly until 9 months post-transplant, followed by quarterly screening until 24 months post-transplant, to identify patients fulfilling the clinical diagnosis of BK polyomavirus nephropathy. Vaccines are lacking, and drugs with presumed antiviral activity have not proven effective for prevention.

PROGNOSIS

After reducing immunosuppression, plasma viral loads decline in 90% of kidney transplant patients within 6 to 12 months, but allograft rejection may occur in 10% of patients. Longer-term outcomes may be adversely affected by smoldering viral replication, T-cell- and/or antibody-mediated rejection, interstitial fibrosis, and tubular atrophy, all of which promote premature allograft failure within 10 years (Chapter 117). Re-transplantation has been successful after several months of reduced or discontinued immunosuppression and clearance of BK polyomavirus-DNAemia, but recurrent disease may occur.

BK Polyomavirus–Associated Hemorrhagic Cystitis

DEFINITION AND EPIDEMIOLOGY

BK polyomavirus–associated hemorrhagic cystitis describes the triad of painful macrohematuria, high-level viral replication, and denudation and inflammation of the bladder wall.[10] The disease affects 5 to 25% of patients who undergo allogeneic hematopoietic cell transplantation but rarely occurs in recipients of autologous transplants or other immunocompromised patients. Risk factors include myeloablative conditioning; exposure to cyclophosphamide or busulfan; a mismatched, unrelated, or haploidentical hematopoietic cell transplantation donor; or umbilical cord blood transplantation. The onset of the disease is typically at 2 to 8 weeks (range 1 week to 6 months) after engraftment of the allogeneic transplant.[11] In North America and Europe, the annual incidence is approximately 1000 cases per year.

PATHOBIOLOGY

Hematopoietic cell transplantation conditioning regimens abrogate BK polyomavirus–specific immune control and lead to BK polyomavirus viruria at greater than 10 million copies/mL. Of note is that such high viruria levels do not cause symptoms in other clinical settings such as kidney transplantation. When radiation or urotoxic drugs (e.g., cyclophosphamide and ifosfamide) cause subclinical damage to the bladder, BK polyomavirus causes further cytopathic damage, which leads to inflammatory exacerbation, reminiscent of the immune reconstitution inflammatory syndrome (IRIS) after engraftment.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

BK polyomavirus–associated hemorrhagic cystitis presents with the clinical signs of cystitis (e.g., dysuria, urinary frequency, urgency, lower abdominal pain; Chapter 263) and macrohematuria, typically in the peri-engraftment period after allogeneic hematopoietic cell transplantation. Macrohematuria may progress to clot formation, bladder obstruction, and postrenal failure.

The clinical diagnosis of BK polyomavirus-associated hemorrhagic cystitis requires the triad of: clinical signs of cystitis, macrohematuria, and high-level viruria (>10 million copies/mL). Ultrasound or magnetic resonance imaging (MRI) can detect larger clots, urinary retention, hydronephrosis, and involvement of the ureteric and bladder wall. The differential diagnosis includes early-onset hemorrhagic cystitis owing to cyclophosphamide within 1 to 7 days of urotoxic conditioning, other bacterial infections, viruses (e.g., cytomegalovirus, herpes simplex, adenovirus), or parasites, as well as non-infectious causes such as graft-versus-host disease, bleeding disorders, irritation from catheters or stents, and primary or metastatic malignancies.

TREATMENT AND PREVENTION

The treatment of BK polyomavirus–associated hemorrhagic cystitis consists of analgesics (Table 26-4) for symptom relief and supportive therapy, hyperhydration, bladder irrigation, platelet and red blood cell transfusions, and urologic interventions for post–renal obstruction or life-threatening bleeding. Reducing immunosuppression is not recommended because it may precipitate or exacerbate graft-versus-host disease. Fluoroquinolones, leflunomide, brincidofovir, systemic or intravesical cidofovir, and hyperbaric oxygen therapy have been tried in uncontrolled studies but cannot be recommended due to side effects, toxicity, and lack of consistent responses.

Hyperhydration combined with forced diuresis to avoid volume overload can reduce early-onset hemorrhagic cystitis and diminish urotoxic damage of the bladder epithelium. No other preventive approach has evidence to support its efficacy and safety.

PROGNOSIS

About 50% of cases resolve by 3 weeks and 75% by 6 weeks. At 9 weeks, about 10% of patients have persistent disease, and another 10% will die with ongoing disease.

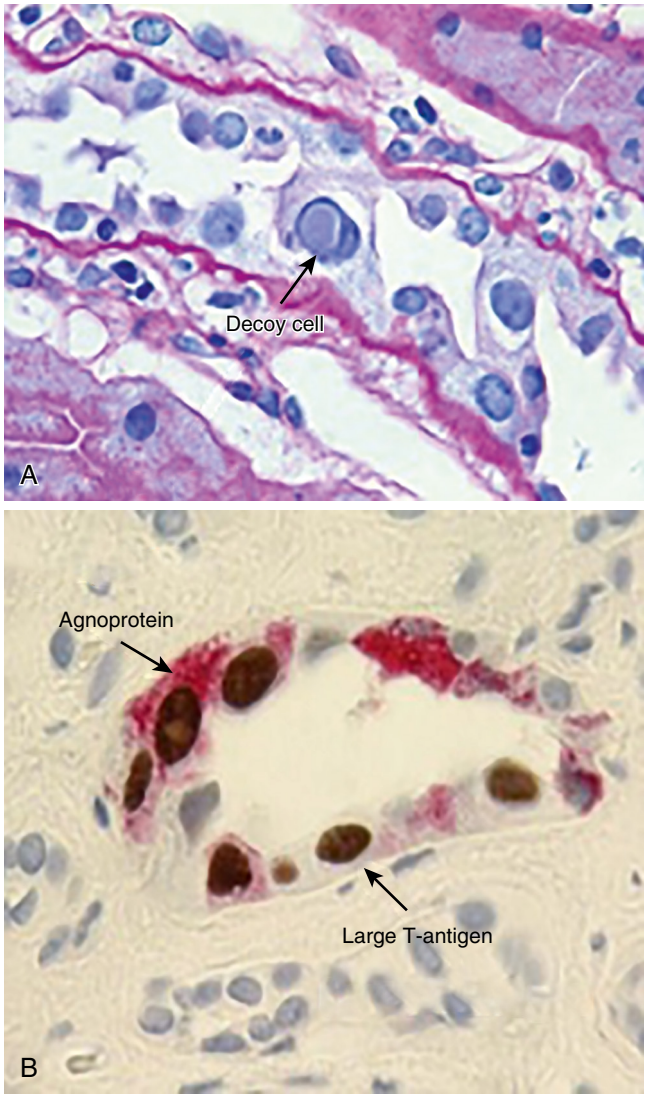
BK Polyomavirus–Associated Urothelial Cancer

DEFINITION AND EPIDEMIOLOGY

BK polyomavirus–associated cancers encompass carcinoma in situ, locally invasive carcinoma, metastasizing carcinoma of the urothelium (transitional cell carcinoma), or, less frequently, tumors of the collecting duct. BK polyomavirus–associated urothelial cancers affect approximately 0.1% of kidney transplant patients and arise 5 to 10 years after transplantation. A history of prolonged immunologically uncontrolled high-level BK polyomavirus–replication or BK polyomavirus nephropathy significantly increases the relative risk by approximately 10-fold.

PATHOBIOLOGY

In BK polyomavirus–associated urothelial cancer, viral tumor antigens appear to induce a phenotype similar to what is seen in BK polyomavirus–negative high-grade urothelial carcinomas (Chapter 182), with mutations in fibroblast growth factor-3 and related downstream tyrosine kinase signaling, as well as inactivation of pRB and p53 function. Subsequent genetic changes and chromosomal instability may remove the dependence on viral tumor antigens, thereby permitting the cancer to progress without expression of the viral tumor antigen.



E-FIGURE 341-1. **BK Polyomavirus nephropathy in a kidney allograft biopsy. A,** Renal tubule in tangential cut showing rounded enlarged tubular cells with prominent nucleus and intranuclear ground-glass inclusions. Inflammatory infiltrates are seen in the interstitium and in the epithelial tubular lining with mononuclear cells and granulocytes. (Hematoxylin and eosin stain, magnification 1000×) **B,** Renal tubule in cross-sectional cut showing BK polyomavirus replication side-by-side in early and late phase by immunohistochemistry for the cytoplasmic agnoprotein *(red)* and the nuclear large tumor antigen *(brown),* partly displaced by intranuclear inclusions *(light brown)* (magnification 1000×). (From Leuenberger D, Andresen PA, Gosert R, et al. Human polyomavirus type 1 [BK virus] agnoprotein is abundantly expressed but immunologically ignored. *Clin Vaccine Immunol*. 2007;14:959-968.)

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical manifestations of BK polyomavirus–associated urothelial cancers are similar to other urothelial cancers (Chapter 182). Depending on tumor location and stage, microhematuria or macrohematuria are often accompanied by an abnormal voiding sensation, intermittent obstruction, hydronephrosis, and lymphadenopathy.

BK polyomavirus–associated cancers are diagnosed by biopsy demonstrating expression of the large viral tumor antigen. In kidney transplant patients, the BK polyomavirus–associated cancer cells are typically donor-derived, presumably because transformed cells from the renal allograft nephropathy may seed the bladder.

TREATMENT AND PREVENTION

In addition to standard therapy for the tumors (see Chapter 182), attention should focus on reducing immunosuppression, even if the allograft needs to be abandoned, to ensure the patient's survival.[12] In immunocompromised and, particularly, kidney transplant patients, occupational and leisure exposure to urotoxic substances (Chapter 106) should be avoided, and smoking should be discontinued. Avoiding prolonged high-level BK polyomavirus–replication and nephropathy should be attempted by screening kidney transplant recipients for BK polyomavirus–DNAemia and by prompt reduction of immunosuppression to restore immune control over virally induced urothelial cancers.

PROGNOSIS

The prognosis of BK polyomavirus–associated urothelial cancers in kidney transplant patients depends on tumor stage, location, and invasiveness. Recurrences are frequent, typically occur within 12 months, and often linked to the inability to reduce immunosuppression.

JC POLYOMAVIRUS

JC polyomavirus causes progressive multifocal leukoencephalopathy, which is a demyelinating, often fatal brain disease in immunocompromised patients (e.g., patients with human immunodeficiency virus [HIV]/acquired immunodeficiency syndrome [AIDS]), hematologic malignancies, and patients treated with potent biologics and small-molecule inhibitors. JC polyomavirus also has been linked to rare cases of nephropathy, encephalopathy, meningoencephalitis, and hemorrhagic cystitis. JC polyomavirus is associated with colon cancers, a variety of brain cancers, and urothelial cancer.

In the general adult population, the seroprevalence of JC polyomavirus is about 50 to 60%, but rates of more than 90% are seen in people living with HIV. Asymptomatic urinary shedding of JC polyomavirus is detectable in about one third of healthy seropositive persons at slightly higher levels than BK polyomavirus (about 50,000 copies/mL). Urine JC polyomavirus loads do not increase in immunocompromised patients to the same extent as seen for BK polyomavirus, except in kidney transplant recipients who develop JC polyomavirus nephropathy. Despite a 70% genomic homology with BK polyomavirus, there is little cross-reactivity of capsid antibodies to the two viruses, whereas cross-reactivity at the T-cell level is considerable and has been used for experimental adoptive T-cell therapies.

JC Polyomavirus–Associated Progressive Multifocal Leukoencephalopathy

DEFINITION AND EPIDEMIOLOGY

Progressive multifocal leukoencephalopathy is a demyelinating brain disease caused by lytic replication of JC polyomavirus in oligodendrocytes that produce the myelin sheath in the subcortical layers and rarely neurons of the gray matter. Nearly all patients with progressive multifocal leukoencephalopathy are seropositive for JC polyomavirus at the time of diagnosis, thereby suggesting that the disease arises despite the presence of virus-specific antibodies. Impaired cellular immune control in the brain seems to play a central role.

The incidence of progressive multifocal leukoencephalopathy in the general population is about 0.3 per 100,000 person years in North America and Europe, but it is 10 to 1000-fold higher in patients who have conditions or treatments that profoundly interfere with T- and B-cell immunity, such as lymphoproliferative diseases.[13] The incidence of progressive multifocal leukoencephalopathy among HIV-AIDS patients in the era before effective antiretroviral therapy was about 2.4 per 1000 patient years, reaching a prevalence of 1% to 7%. The incidence among patients with relapsing-remitting multiple sclerosis treated with natalizumab therapy is about 2.13 per 1000 patient years overall, increasing to 11.1 per 1000 patient years among JC polyomavirus–seropositive patients who are treated for longer than 24 months.[14] Newer potent biologicals and small molecule inhibitors that interfere with T and B cell function also are associated with progressive multifocal leukoencephalopathy.[15] Rare cases of progressive multifocal leukoencephalopathy arise in people without known immunodeficiencies, sometimes related to idiopathic CD4 lymphocytopenia or hitherto undiagnosed hematologic abnormalities.

PATHOBIOLOGY

JC polyomavirus replication in oligodendrocytes leads to cell lysis and loss of the myelin sheaths that are required for the function of neural axons. The affected oligodendrocytes lose their characteristic halo and increase in size, with prominently enlarged nuclei and eosinophilic intranuclear inclusions. On electron microscopy, intranuclear virions of 45 nm in diameter are seen. JC polyomavirus genomes in brain tissue and cerebrospinal fluid (CSF) are characterized by rearrangements of the noncoding control region that increase viral replication. As viral replication and demyelination zones expand, lesions with acellular fibrotic centers and increasing atrophy can range from less than 1 mm to several centimeters. Multiple replication zones coalesce and rapidly expand along linear axon-myelin structures in ipsilateral and contralateral subcortex. The lesions typically start in the subcortical white matter and less frequently in the cerebellum or basal ganglia. Infection of neurons defines a separate cerebellar entity called granule cell neuronopathy.

CLINICAL MANIFESTATIONS

The symptoms and signs of progressive multifocal leukoencephalopathy depend on the location and the extent of the lesions in the brain.[16] Sensory or motor deficits of the hands or visual impairments, which reflect involvement of the parietal or posterior brain, respectively, may be noticed very early. Most patients develop progressive motor weakness, followed by speech abnormalities, cognitive deficits, headache, ataxia, aphasia, and cranial nerve deficits.[17] Ophthalmologic symptoms include optic agnosia, oculomotor abnormalities, and cortical blindness. Seizures have been reported at variable rates and are more frequent in association with gadolinium enhancing cortical lesions linked to inflammation.

DIAGNOSIS

In any immunocompromised patient with new-onset focal neurologic deficits or seizures, progressive multifocal leukoencephalopathy is an important possible diagnosis. MRI is the non-invasive diagnostic procedure of choice to identify brain lesions, which are enhancing by fluid-attenuated inversion recovery (FLAIR) and/or T2-weighted imaging, revealing inflammatory signals by T1-gadolinium MRI upon immune reconstitution (Fig. 341-1). HIV/AIDS patients and rituximab-treated patients may show only little or no gadolinium enhancement. Screening of patients with multiple sclerosis can identify early stage or even presymptomatic progressive multifocal leukoencephalopathy.

Detection of the JC polyomavirus–DNA genome in the CSF is sufficient for a laboratory-confirmed diagnosis of presumptive progressive multifocal leukoencephalopathy, but 10 to 30% of eventually proven cases of progressive multifocal leukoencephalopathy remain JC polyomavirus–DNA negative despite repeated CSF sampling. Other CSF studies provide little information. Pleocytosis is absent or mild at fewer than 50 cells/μL, and levels of glucose, lactate, and protein are typically nondiagnostic. Intrathecal antibodies and oligoclonal bands may be detectable on testing performed at specialized settings. Stereotactic brain biopsies, which are rarely indicated unless an alternative diagnosis (such as recurrent multiple sclerosis, primary cerebral lymphoma, toxoplasma encephalitis or other bacterial, fungal, or parasitic diseases) is likely, can make the definitive diagnosis by showing the triad of demyelination in the white matter, compatible cytopathic alterations, and JC polyomavirus involvement by specific immunohistochemistry or in situ hybridization.

TREATMENT

No antiviral agents have proven clinical efficacy for progressive multifocal leukoencephalopathy even though some drugs (e.g., cidofovir, brincidofovir, cytarabine, topotecan, mefloquine, and mirtazapine) inhibit JC polyomavirus replication in vitro. In clinical practice, mirtazapine is frequently prescribed after consideration of drug-drug interactions and escalated from 15 mg daily to the highest tolerated dose of 45 mg daily to treat diagnosis-associated depression

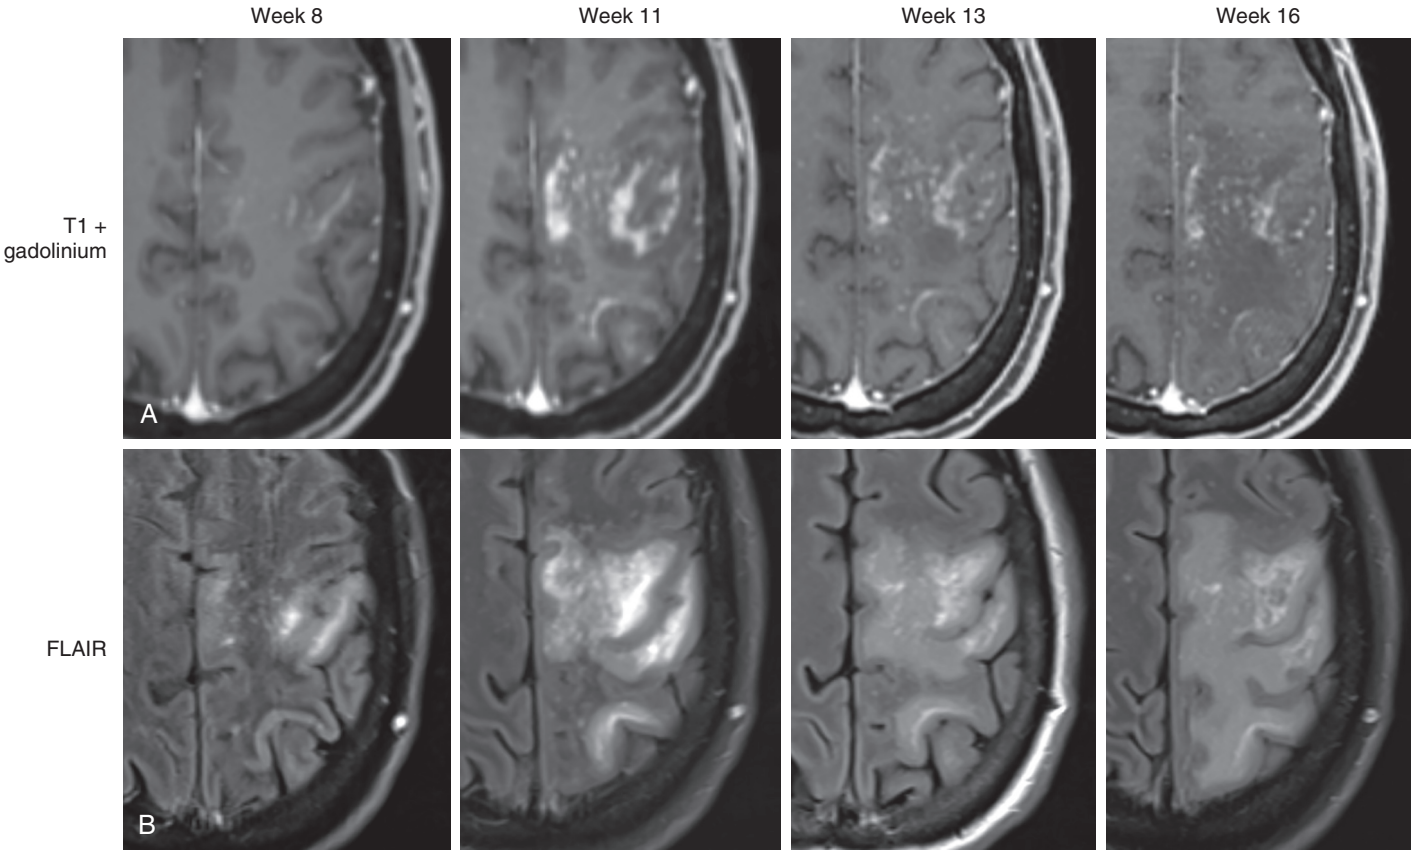


FIGURE 341-1. Cranial magnetic resonance images of progressive multifocal encephalopathy unmasked by the immune reconstitution inflammatory syndrome (PML-IRIS) in a patient with HIV/AIDS. After 8 weeks of combination viral suppressive therapy and recovery of CD4 cells from 20 to 365/μL, the lesions worsened and then improved. **A,** A T1-weighted image with gadolinium enhancement; **B,** Fluid-attenuated inversion recovery (FLAIR).

and possibly to interfere with the entry of JC polyomavirus into glial cells. The main approach to treatment is to regain JC polyomavirus–specific immune control in the brain by reversing the underlying cause of immunodeficiency by suppressing HIV-replication using combination antiretroviral therapy (Chapter 357), discontinuing natalizumab in patients with multiple sclerosis (Chapter 380), or reducing immunosuppression in solid organ transplant recipients whenever possible.[18] When immune reconstitution cannot be readily achieved, experimental approaches to enhance JC polyomavirus–specific immunity include cytokines (e.g., interleukin-2, filgrastim, interleukin-7 alone or in combination with Vp1-capsid or peptide vaccination), intravenous infusions of neutralizing monoclonal antibodies, immune checkpoint inhibitors, and adoptive transfer of related or third-party donor-derived T cells active against JC polyomavirus.[19,20]

Upon brisk recovery of CD4 and CD8 T-cell functions and their homing to the sites of JC polyomavirus replication in the brain, paradoxical clinical worsening can occur due to the immune reconstitution inflammatory syndrome (IRIS). IRIS can be seen as early as 1 to 2 weeks and up to several months after the introduction of antiretroviral treatment in 30% of HIV/AIDS patients but is encountered in nearly all multiple sclerosis patients after discontinuing natalizumab. IRIS can lead to brain swelling with mass effect, herniation, and even death. Intravenous methylprednisolone (1 g/kg for 5 to 7 days) or dexamethasone (6 to 8 mg 4 times daily for 7 to 10 days) followed by oral tapering can stabilize or improve clinical symptoms and radiologic abnormalities, but at the expense of recurring JC polyomavirus replication. Anecdotal evidence supports high-dose, steroid-saving intravenous immunoglobulin (0.5 to 2.0 g/kg 3 times per week for 3 weeks, followed by tapering).

PREVENTION

The prevention of progressive multifocal leukoencephalopathy is difficult because of its seemingly sporadic occurrence in immunocompromised patients. For HIV/AIDS patients, antiretroviral therapy (Chapter 357) to suppress HIV replication to undetectable levels has reduced the incidence of the disease to rare late presenters. For patients who have multiple sclerosis (Chapter 380) and qualify for natalizumab therapy, use of the drug requires careful patient counseling and MRI surveillance. For example, in patients who have multiple sclerosis with prior immunosuppressive treatment and JC polyomavirus–positive serology indicative of persistent infection, the risk of progressive multifocal leukoencephalopathy after 24 months of natalizumab treatment is 4 to 10 per 1000 patients, so screening MRI should be performed every 3 to 4 months. For patients without prior immunosuppressive treatment and no JC polyomavirus antibody levels, the risk of progressive multifocal leukoencephalopathy is less than 0.1 per 1000 patients, and screening patients for JC polyomavirus seroconversion is recommended to identify patients for 3- to 4-monthly MRI screening for progressive multifocal leukoencephalopathy.

PROGNOSIS

The prognosis of progressive multifocal leukoencephalopathy is closely linked to the extent and location of involvement at the time of diagnosis, the underlying cause of immunodeficiency, and the ability to revert, modify, or compensate for the missing JC polyomavirus–specific immune control. Approximately one-third of patients recover with no or only slight disabilities, one-third have significant disabilities, and one-third die within 12 months. Somewhat better outcomes are observed for natalizumab-treated patients with multiple sclerosis, especially if they are asymptomatic or have only minimal involvement at the time of diagnosis. The poorest outcomes, with fatality in more than 90% of cases, are seen in patients with hematologic malignancies or in heart or lung transplant recipients because of the inability to induce timely immune recovery. At the other extreme, the immune reconstitution inflammatory syndrome may significantly complicate the course and impair outcomes because of the need to treat with corticosteroids that facilitate viral replication. Eventually, the affected brain areas convert into fibrotic zones with progressive atrophy visible on MRI, but some functional compensation may be possible by training other domains, especially in younger patients.

JC Polyomavirus–Associated Nephropathy

JC polyomavirus–associated nephropathy describes damage to nephrons when replication of JC polyomavirus in renal tubular epithelial cells leads to progressive functional decline and irreversible end-stage renal failure. JC polyomavirus nephropathy occurs in less than 1% of kidney transplant patients. Affected patients have high-level JC polyomavirus viruria with urine viral loads greater than 10 million copies/mL.

JC polyomavirus nephropathy is asymptomatic, despite signs of declining renal function. The disease may be suspected when the more common BK polyomavirus–DNA is undetectable in blood or urine. Kidney biopsy is required to make the diagnosis.

Treatment is to reduce immunosuppression, but at the risk of precipitating acute rejection. No antiviral or vaccine is available for prevention. Notably, the risk of progressive multifocal leukoencephalopathy does not seem to be increased among patients with JC polyomavirus nephropathy.

MERKEL CELL POLYOMAVIRUS

Merkel cell polyomavirus is part of the general human skin microbiome, with a prevalence ranging from 30 to 80%. Higher rates in adults over age 60 years suggest continued life-time exposure.

Merkel Cell Polyomavirus–Associated Carcinoma

Merkel cell carcinoma is a rapidly growing, metastasizing skin malignancy with neuroendocrine and proprioceptive features. The tumors harbor chromosomally integrated Merkel cell polyomavirus genomes in 80 to 90% of cases. The incidence in the United States has increased to about 0.7 cases per 100,000 person-years. The key risk factors are fair skin, chronic sun exposure, increasing age, and immunodeficiency. More than 95% of Merkel cell carcinomas occur in persons of White ethnicity, showing an approximately three-fold rise in incidence per decade of age. Males are affected about twice as often as females. Other risk factors include immunodeficiency from HIV/AIDS, hematologic malignancies, and transplantation. For example, rates of Merkel cell carcinoma are approximately 20 times higher among recipients of solid organ transplants.

The pathogenesis of Merkel cell carcinoma is thought to involve Merkel cell polyomavirus infection of the epidermis, possibly via sites of reduced integrity or damage. Extensive viral replication in systemically immunocompromised hosts synergizes with local effects of ultraviolet light to weaken local immunity and induce chromosomal integration.[21]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Merkel cell carcinoma presents as asymptomatic, rapidly growing shiny bluish pink nodules with a smooth surface, typically located in chronically sun-exposed areas of the head, neck, and upper extremities (Fig. 341-2A),[22] and less frequently on the trunk and lower extremities. Regional lymph nodes may be enlarged.

The diagnosis is based on histopathology showing dense small uniform round cells with basophilic nuclei and minimal cytoplasm organized in trabecular, intermediate, small cell, and mixed type-denoted structures (see Fig. 341-2B).[23] Staining for Merkel cell polyomavirus large tumor antigen and cytokeratin 20 expression is often used for diagnosis. Because of its high prevalence in the general population, detecting the Merkel cell polyomavirus genome in a skin biopsy is not pathognomonic for Merkel cell carcinoma unless replication-crippling mutations or chromosomal integration are documented.

TREATMENT AND PREVENTION

Treatment is guided by staging at the time of diagnosis.[24] Stage I is defined as a tumor size of less than 2 cm without nodal or distant metastasis. Stage IIA is a larger tumor but without local invasion, whereas stage IIB is defined as a tumor of any size invading local structures but is not accompanied by nodal involvement or distant metastasis. Stage III is defined by lymph node involvement, regardless of tumor size, but without distant metastasis. Stage IV is defined by the presence of distant metastases regardless of the size of the tumor or lymph node involvement.

Complete surgical removal of the tumor and of sentinel lymph nodes is recommended for initial therapy and staging. If the primary tumor cannot be completely removed or if sentinel lymph nodes are positive, regional lymph node resection and radiation therapy is recommended. In immunosuppressed patients, immunosuppression should be reduced if possible according to the underlying condition. Immunotherapy with immune check-point inhibition (e.g., the PD-1 inhibitors nivolumab or pembrolizumab, PD-1 ligand blockade by avelumab, or the CTLA-4 inhibitor ipilimumab) under expert supervision have dramatically improved outcomes and are becoming standard of care. Chemotherapy is recommended when immunotherapy fails and for metastatic disease or recurrent disease, either alone or in combination with local radiotherapy. Experimental therapies using MCPyV-specific adoptive T cells or targeting growth factor receptors or tyrosine kinase signaling pathway are being explored in clinical trials.

Strict avoidance of sun exposure is recommended in elderly, immunosenescent, and immunocompromised patients. Correcting the underlying immunodeficiency can prevent Merkel cell carcinoma in HIV/AIDS patients but may not be feasible in other patients.

PROGNOSIS

Invasiveness and rapid growth are key determinants of outcome, and 5-year overall survival ranges from approximately 80% in stage I disease to less than 20% in stage IV disease. Lesions on the scalp tend to be larger than 5 cm and have an increased risk of distant metastasis, whereas tumors on the lips are more likely to invade local structures. Merkel cell polyomavirus–positive patients have a better prognosis presumably because expression of the viral tumor antigen enhances recognition and killing by CD8 T cells. Patients who have Merkel cell carcinoma also are at increased risk of other malignancies.

OTHER CUTANEOUS HUMAN POLYOMAVIRUS–ASSOCIATED DISEASES

Human Polyomavirus 6 and 7–Associated Pruritic Hyperproliferative Keratinopathy

The seroprevalence of human polyomavirus 7 in the general population increases substantially with age from 40% at age 20 years to more than 70% after age 70 years, whereas the seroprevalence of human polyomavirus 6 is already 80% by early adolescence. In profoundly immunocompromised patients, such as after heart or lung transplantation, a widespread maculopapular eruption has been described predominantly on the trunk and the extremities but sparing palmoplantar surfaces, facial, axillary, and inguinal areas. Skin biopsy shows dyskeratotic cells in the epidermis and layers of nucleated keratinocytes in the stratum corneum. Immunohistochemistry demonstrates replicating human polyomavirus 7 or human polyomavirus 6.

No treatment has proven efficacious. Oral antihistamines, topical pramoxine, and emollients can be used for symptomatic treatment of pruritus (Table 403-10). Systemic acitretin (25 mg daily or twice daily) has shown anecdotal success, whereas topical corticosteroids are ineffective or even deleterious. Reducing immunosuppression may be helpful. Ultraviolet light therapies should be avoided. Despite treatment, sleep-disturbing pruritus and the extensive manifestations severely decrease quality of life.

Polyomavirus-Associated Trichodysplasia Spinulosa

In the general population, the seroprevalence for trichodysplasia spinulosa polyomavirus (human polyomavirus 8) increases from 20% in children younger than age 10 years to more than 80% in adults older than age 50 years. The prevalence of trichodysplasia spinulosa polyomavirus in skin swabs or in blood samples from healthy blood donors is low, ranging from 0.3% to 3.0%. The disease is rare, with fewer than 100 cases described, mostly in patients who have hematologic malignancies or who are on chronic immunosuppressive medications and who develop primary viral infection.

Affected follicular keratinocytes are characterized by hyperproliferation with enlarged eosinophilic trichohyaline granules and enlarged cell nuclei with intranuclear inclusions of polyomavirus particles. Molecular testing reveals high loads of trichodysplasia spinulosa polyomavirus–DNA.

The key features of trichodysplasia spinulosa are painless folliculocentric papular eruptions in the face, spicule formation with distention of skin pores, loss of hair formation most prominently visible by disappearance of eyebrows and eye lashes, and progressive thickening of the skin. The clinical diagnosis is confirmed by a skin biopsy revealing dilated follicles, keratin plugs, abnormal differentiation of inner hair root sheaths, absent hair bulbs, and immunohistochemistry that detects viral protein expression.

Topical cidofovir (1 to 3%) can provide partial response, but topical steroids are ineffective. Reduced immunosuppression can be helpful, but the disease persists or progresses until immune control becomes effective. Physical removal of spicula may provide some cosmetic relief, but the risk of developing scars versus the benefit of stimulating immunity is uncertain. The disease is not life-threatening, but disfiguring skin manifestations cause significant distress.

342 PARVOVIRUS

NEAL S. YOUNG

DEFINITION

B19 parvovirus, which was discovered in the mid-1970s by electron microscopy of an anomalous precipitin reaction of a blood donor's serum (occupying position 19 in plate B), was first linked to human disease by the observation of virus-specific immunoglobulin M (IgM) antibody or the virus itself in the sera of sickle cell disease patients suffering transient aplastic crisis (Chapter 149). The common illness caused by the virus was identified later during outbreaks of fifth disease, a highly contagious rash illness of childhood long suspected of having a viral etiology. The ability of parvovirus to persist and to be manifested as an isolated hematologic syndrome was demonstrated by the presence of the virus in fetal liver at autopsy of hydropic newborns and in immunosuppressed patients with chronic pure red cell aplasia (Chapter 151).[1]

The Pathogen

The parvoviruses, which are small icosahedral capsids of about 25 nm, contain a limited genome of single-stranded DNA. The approximately 5600 nucleotides of B19 parvovirus show remarkably little sequence variation among isolates; two variants, V9 and A6, are of uncertain clinical significance.

The Parvoviridae family contains many pathogenic animal viruses: feline panleukopenia virus, the cause of a fatal agranulocytosis in cats; canine parvovirus, which probably arose from the cat virus as a host range variant in the 1970s to produce a global pandemic and can cause fatal myocarditis in puppies; Aleutian mink virus infection, a model of immune complex disease; and porcine parvovirus, responsible for fetal wastage in pig litters. Antibodies to human adeno-associated viruses, which are dependoparvoviruses that are now popular as gene therapy vectors, occur naturally in humans, but B19 is the only parvovirus known to be pathogenic in humans.

EPIDEMIOLOGY

B19 infection is global; infectivity rates, inferred from the presence of antiparvovirus IgG antibody in sera, are similar worldwide. Only isolated populations, such as Amazonian tribesman and residents of remote islands off the coast of Africa, have escaped exposure. B19 parvovirus infection is common in childhood, and half of 15-year-old adolescents have specific antiparvovirus B19 antibodies. Infection continues throughout adult life, and most elderly people are seropositive. In temperate climates, infections occur in the spring, with small epidemics every few years being typical. Transmission is respiratory by droplet spread, and secondary infection rates among household contacts are high. Nosocomial infection can occur, and B19 parvovirus has been transmitted in blood products, especially pooled components such as factor VIII and IX concentrates. Producers of plasma derivatives now voluntarily screen by quantitative measurement of B19 DNA to reduce the risk for iatrogenic transmission. The lack of a lipid envelope and the stable DNA genome make parvoviruses notoriously resistant to heat inactivation and solvent detergents.

342 PARVOVIRUS

NEAL S. YOUNG

DEFINITION

B19 parvovirus, which was discovered in the mid-1970s by electron microscopy of an anomalous precipitin reaction of a blood donor's serum (occupying position 19 in plate B), was first linked to human disease by the observation of virus-specific immunoglobulin M (IgM) antibody or the virus itself in the sera of sickle cell disease patients suffering transient aplastic crisis (Chapter 149). The common illness caused by the virus was identified later during outbreaks of fifth disease, a highly contagious rash illness of childhood long suspected of having a viral etiology. The ability of parvovirus to persist and to be manifested as an isolated hematologic syndrome was demonstrated by the presence of the virus in fetal liver at autopsy of hydropic newborns and in immunosuppressed patients with chronic pure red cell aplasia (Chapter 151).[1]

The Pathogen

The parvoviruses, which are small icosahedral capsids of about 25 nm, contain a limited genome of single-stranded DNA. The approximately 5600 nucleotides of B19 parvovirus show remarkably little sequence variation among isolates; two variants, V9 and A6, are of uncertain clinical significance.

The Parvoviridae family contains many pathogenic animal viruses: feline panleukopenia virus, the cause of a fatal agranulocytosis in cats; canine parvovirus, which probably arose from the cat virus as a host range variant in the 1970s to produce a global pandemic and can cause fatal myocarditis in puppies; Aleutian mink virus infection, a model of immune complex disease; and porcine parvovirus, responsible for fetal wastage in pig litters. Antibodies to human adeno-associated viruses, which are dependoparvoviruses that are now popular as gene therapy vectors, occur naturally in humans, but B19 is the only parvovirus known to be pathogenic in humans.

EPIDEMIOLOGY

B19 infection is global; infectivity rates, inferred from the presence of antiparvovirus IgG antibody in sera, are similar worldwide. Only isolated populations, such as Amazonian tribesman and residents of remote islands off the coast of Africa, have escaped exposure. B19 parvovirus infection is common in childhood, and half of 15-year-old adolescents have specific antiparvovirus B19 antibodies. Infection continues throughout adult life, and most elderly people are seropositive. In temperate climates, infections occur in the spring, with small epidemics every few years being typical. Transmission is respiratory by droplet spread, and secondary infection rates among household contacts are high. Nosocomial infection can occur, and B19 parvovirus has been transmitted in blood products, especially pooled components such as factor VIII and IX concentrates. Producers of plasma derivatives now voluntarily screen by quantitative measurement of B19 DNA to reduce the risk for iatrogenic transmission. The lack of a lipid envelope and the stable DNA genome make parvoviruses notoriously resistant to heat inactivation and solvent detergents.

ABSTRACT

Parvovirus B19 causes diverse important human diseases. The target of the virus is the erythroid progenitor cell, and the neutralizing antibody response dominates effective immunity. Acute infection in normal persons is fifth disease, which is a contagious rash illness in childhood and often a rheumatic syndrome in adults. Under conditions of stressed red cell production, B19 causes transient aplastic crisis, typically a severe worsening of anemia in a patient with sickle cell disease. In immunocompromised individuals, viral infection is persistent and can cause pure red cell aplasia. Infection of the mid-trimester fetus can result in hydrops fetalis.

hydrops
fifth disease
P antigen
globoside

PATHOBIOLOGY

The biology of the Parvoviridae makes them dependent on helper function from host cells or other viruses. The autonomous parvoviruses propagate in actively dividing cells; the family Parvoviridae includes many disease-causing animal parvoviruses. Adeno-associated viruses grow in tissue cultures infected with adenoviruses and herpesviruses and are popular vectors for gene transduction and therapy. B19 is the type member of the *Erythrovirus* genus, which includes similar simian viruses, all of which are best propagated in the erythroid progenitor cells that are responsible for red blood cell production in the bone marrow. Active replication of virus can be detected by the presence of double-stranded intermediate forms using simple DNA hybridization methods. The transcription map of the erythroviruses differs markedly from that of other Parvoviridae. Only a few genes produce proteins of known function. Many antigenic determinants recognized by the host immune system are located in helical loops that form the surface of each capsomere. Most of the capsid is composed of a major structural protein, called VP2, but about 5% of the capsid is the minor structural protein, VP1, which differs from VP2 by an additional 226 amino acids at the amino terminus; this VP1 unique region is located external to the capsid surface and contains linear epitopes recognized by neutralizing antibodies. VP1, which is not only immunodominant but also critical for viral entry into permissive cells, also has phospholipase A2 activity that promotes release of virions from infected cells.

The only known natural host cell of B19 parvovirus is the human erythroid progenitor. The tropism of the virus for an erythroid cell results from its cellular receptor, globoside, a neutral glycolipid also known as erythrocyte P antigen. Rare individuals with the p phenotype, who congenitally lack globoside on their erythrocytes, are genetically insusceptible to B19 parvovirus infection; they show no serologic evidence of previous infection, and their marrow erythroid progenitors proliferate normally in the presence of high concentrations of virus. Parvovirus kills erythroid progenitors by expression of its nonstructural protein, and it is possible that some cells, such as megakaryocytes, may be lysed by restricted expression of viral proteins in the absence of viral propagation. B19 can be efficiently propagated in tissue culture of primary human hematopoietic cells in which erythropoietic differentiation is stimulated by erythropoietin. There is evidence that parvovirus DNA can integrate into the genome of erythroid precursor cells in tissue culture.

The humoral immune response is dominant in B19 parvovirus infection. Levels of the chemokine CXCL-10 rise with acute viremia. Natural antibody production correlates with disappearance of the virus from blood, and the presence of IgG appears to confer lasting protection against a second infection. Parvovirus infection can persist if immunoglobulin production is defective such that antibody fails to neutralize the virus; reactivity of antibodies to the unique amino-terminal region of VP1 is especially important.

CLINICAL MANIFESTATIONS

Most B19 parvovirus infections are asymptomatic. However, infections can precipitate specific clinical syndromes such as erythema infections and pure red cell aplasia, as well as a variety of signs and symptoms that may be difficult to distinguish from other viral infections.[2-4]

Fifth Disease

The most common clinical manifestation of infection is erythema infectiosum, or fifth disease, a rash illness of childhood characterized by a "slapped cheek" appearance (Fig. 342-1).[5] In adult volunteers inoculated intranasally with B19, nonspecific influenza-like complaints occur early along with viremia, and such symptoms are also noted with natural infection.[6] The cutaneous eruption a week later corresponds with the appearance of antiviral antibodies. These more specific symptoms of B19 parvovirus infection are secondary to immune complex formation and deposition. The rash of fifth disease is typically evanescent, and recurrences can be provoked by sunlight, heat, emotion, or exercise. Fifth disease can be easily confused with rubella (Chapter 339). In adults, the rash is less characteristic, can present as palpable purpura, may be associated with pruritus in up to 50% of patients, and can be difficult to visualize in dark-skinned individuals.

B19 Arthropathy

In contrast to the mild course in children with fifth disease, acute parvovirus infection in adults, particularly immunocompetent middle-aged women, may cause significant arthropathy.[7] Not only arthralgia but also a true inflammatory arthritis can occur in older patients. Symmetrical joint involvement of the hands, ankles, knees, and wrists may resemble rheumatoid arthritis (Chapter 243), and the test result for rheumatoid factor may be positive. B19 arthropathy usually resolves within a few weeks; joint destruction does not occur. Parvovirus is not the cause of rheumatoid arthritis, but case reports suggest that B19 infection may mimic, precipitate, or worsen a variety of rheumatologic diseases, including juvenile rheumatoid arthritis, systemic lupus erythematosus, and fibromyalgia. Autoantibodies that can appear during infection may be the link between the virus and its immune-mediated manifestations.

Transient Aplastic Crisis

In patients with hematologic malignancies, a recent hematopoietic stem cell transplant, chronic hemolysis, or a high demand for erythrocytes, acute B19 parvovirus infection causes a transient aplastic crisis, which is an abrupt cessation of red blood cell production that exacerbates or, in previously compensated states, provokes severe anemia.[8] Erythropoiesis is temporarily suppressed in all B19 parvovirus infections, but hemoglobin levels remain stable because of the long lifespan of erythrocytes. The anemic crises associated with low or absent reticulocytes in hereditary spherocytosis and sickle cell disease are virtually always secondary to B19 parvovirus infection.

Parvoviremia is present in patients with transient aplastic crisis, and red cell production resumes once antibodies to the virus are produced and the infection is cleared. Transient aplastic crisis is generally a unique event in the patient's life, thereby suggesting induction of long-lasting protective immunity. Although it is self-limited, aplastic crisis often requires transfusion and can lead to severe, occasionally fatal anemia that precipitates heart failure and cerebrovascular accidents. Transient aplastic crisis is associated with a stereotypical bone marrow morphology, absence of maturing erythroid precursors, and the presence of "giant pronormoblasts" (Fig. 342-2) that are the cytopathic effect of parvovirus infection.

White blood cell and platelet counts may fall during transient aplastic crisis, especially in patients with functioning spleens. Occasional cases of agranulocytosis may be due to B19; thrombocytopenia and pancytopenia have been reported, and B19 can precipitate virus-associated hemophagocytic syndrome. In a large series of Egyptian patients with hereditary hemoglobinopathies, B19 infection documented by seroconversion was associated with reversible bone marrow failure, acute kidney injury, and extreme hyperbilirubinemia.[9]

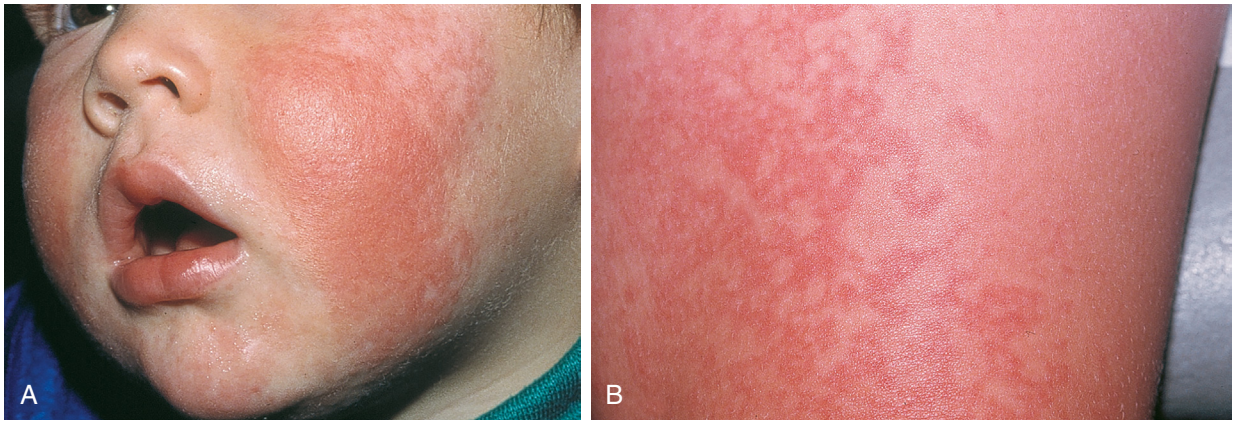

FIGURE 342-1. Erythema infectiosum. B19 infection in a child, manifesting typical prominent erythema of the cheeks ("slapped cheeks") (**A**), followed by lacelike erythema on the extremities (**B**) and buttocks. Historically denoted fifth disease, it is more appropriately termed acute parvovirus infection.

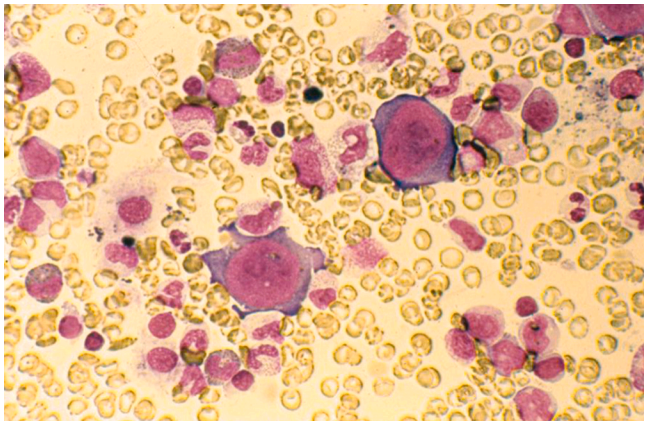

FIGURE 342-2. Bone marrow aspirate of a patient with chronic pure red cell aplasia secondary to persistent B19 parvovirus infection. Mature erythroid precursors are absent, and prominent giant pronormoblasts are typical of B19 infection.

Persistent Infection

In patients who cannot mount an appropriate host antibody response, B19 parvovirus persists in the circulation, often at extremely high levels (>10^{12} genome copies per milliliter). Patients do not develop the clinical features of fifth disease but instead have an entirely hematologic syndrome of pure red cell aplasia. The anemia is severe and requires transfusion; reticulocytes are absent from blood, and erythroid precursors are absent from the bone marrow. Observation of marrow giant pronormoblasts leads to the diagnosis. Failure to produce neutralizing antibodies to B19 parvovirus occurs in patients with congenital immunodeficiency (Nezelof syndrome), with iatrogenic immunodeficiency (from chemotherapy or immunosuppressive drugs), and with acquired immunodeficiency. Pure red cell aplasia secondary to parvovirus has been the first manifestation of acquired immunodeficiency syndrome (AIDS), but this presentation is now uncommon in the era of highly active antiretroviral therapy.

Hydrops Fetalis

B19 parvovirus infection of the pregnant mother followed by transplacental transmission to the fetus can lead to an adverse outcome, either miscarriage or hydrops fetalis.[10] Parvovirus infects the fetal liver, the site of erythrocyte production during early development. Hydrops is the result of severe anemia as well as perhaps myocarditis, contributing to congestive heart failure. Prospective studies have estimated a 30% risk for transplacental infection and 9% risk for fetal loss in women who are exposed to B19 during pregnancy. Infection during the second trimester poses the greatest risk for birth of a hydropic infant; B19 parvovirus accounts for 10 to 20% of all cases of nonimmune hydrops fetalis. The risk for spontaneous abortion resulting from first-trimester infections has been more difficult to quantitate. The likelihood of an infection increases in epidemic years and correlates with the level of contact of the pregnant woman with children. Although most B19 infections during pregnancy do not lead to either loss of the fetus or congenital anomalies, B19 infection is a cause of fetal death. Congenital malformations have not been associated with intrauterine parvovirus infection. However, severe anemia at birth with bone marrow histology consistent with either constitutional pure red cell aplasia (Diamond-Blackfan anemia) or congenital dyserythropoietic anemia has occurred in infants salvaged by in utero blood transfusions or exchange transfusion at birth.

Other Syndromes

Elevated hepatic aminotransferase levels can accompany fifth disease, and parvovirus infection has been associated with severe but usually self-limited hepatitis in some children. The presence of B19 genetic sequences in cardiac tissue has led to a diagnosis of parvovirus myocarditis.[11] Serologic and DNA evidence of B19 infection implicated parvovirus in some patients with necrotizing vasculitis, Kawasaki disease, Henoch-Schönlein purpura, and giant cell arteritis. Glove-and-sock syndrome, an exanthem localized to the hands and feet and consisting of edema, erythema, paresthesia, and pruritus, has been linked to B19. Chronic fatigue syndrome may follow parvovirus infection. Meningitis, encephalitis, and a variety of neurologic complications may occur with fifth disease and parvovirus infection.[12,13]

Subtle late effects of viral infection, not related to persistent infection, may include a worsening of the manifestations of malaria (Chapter 316), especially the severity of anemia. Previous viral infection also has been linked to cerebral infarctions in patients with sickle cell diseases[14] and to arterial ischemic strokes in pediatric populations.

However, false-positive results arise when the diagnosis of infection rests on detection of amplified B19 genome by polymerase chain reactions. Furthermore, B19 parvovirus can persist at low levels in various tissues of normal individuals for many months after infection. For example, whole genome sequencing has detected B19 in 0.12% of individuals without apparent infectious disease, usually but not always at relatively low viral abundance.

TABLE 342-1 DIAGNOSIS OF PARVOVIRUS B19

DISEASE	IgM	IgG	B19 DOT BLOT*	B19 PCR
Fifth disease	+++	++	–	+
Polyarthropathy syndrome	++	+	–	+
Transient aplastic crisis	+/–	+/–	++	++
Persistent anemia	+/–	+/–	++	++
Hydrops/congenital infection	+/–	+	+/–	++
Previous infection	–	++	–	+/–

*Sensitivity about 106 genome copies per milliliter.
Ig = immunoglobulin; PCR = polymerase chain reaction.

DIAGNOSIS

Laboratory diagnosis relies on DNA and serologic testing (Table 342-1). Although virus-specific IgM antibodies are diagnostically positive in almost all cases of fifth disease at initial evaluation and appear within a few days of the onset of transient aplastic crisis, IgM may persist for months after acute infection, IgG circulates later than IgM, generally at the end of the first week of illness. Although titers of IgG are generally highest in the year after an acute infection, substantial interindividual variation and the presence of IgG in a large proportion of the population make measurement of IgG less helpful than other tests for diagnosis of parvovirus.

DNA assays are required to diagnose persistent B19 infection, in which antibody production is absent or minimal. Parvovirus can also be found in the sera early in transient aplastic crisis. Direct hybridization methods are reliable, and they detect clinically relevant viral titers of greater than 10^6 international units (orders of magnitude below levels present in both acute and persistent infection). Gene amplification methods are more sensitive, but low positive results should be interpreted cautiously. Virus can be detected in amniotic fluid, and both virus and IgM antibody to B19 are found in umbilical cord blood; the mother's serum will show seroconversion during pregnancy, but maternal IgM may be absent at the onset of hydrops fetalis.

TREATMENT

Parvovirus infections in normal children and adults do not require specific therapy. Isolation of infected individuals is impractical, with the exception of hospitalized cases. Pure red cell aplasia and the underlying persistent B19 parvovirus infection can be dramatically terminated by discontinuation of immunosuppressive therapy or institution of effective antiretroviral drugs in patients with AIDS. Commercial immunoglobulins are a good source of antibodies to parvovirus, and persistent B19 infection responds to a 2- to 10-day course of IgG at 0.4 g/kg[15] with a prompt decline in serum viral DNA, as measured by hybridization methods, accompanied by reticulocytosis and increased hemoglobin levels. This regimen has been curative in congenital immunodeficiency, but parvovirus in AIDS patients can persist at lower levels.

Immunoglobulin therapy can precipitate fifth disease rash and arthralgia. Chronic arthropathy should be treated symptomatically with anti-inflammatory drugs (Table 26-4), and there is no established role for the administration of immunoglobulin.

PREVENTION

Effective vaccines exist for animal parvoviruses, and human B19 infection should be preventable. A recombinant immunogen for the human virus lacks DNA and is therefore noninfectious; the empty capsids have been engineered to overexpress the highly immunogenic minor structural protein VP1, and a single 2.5-μg dose of empty capsids elicited excellent neutralizing antibody responses in normal

volunteers. Vaccination would prevent transient aplastic crisis in patients with hemoglobinopathies, pure red cell aplasia in some immunodeficient individuals, and hydrops if seronegative mothers were inoculated early in pregnancy. Unfortunately, no vaccine is currently under commercial development.

PROGNOSIS

Most infections resolve without treatment. For patients with pure red cell aplasia, relapses of anemia may require repeated IgG administration. Hydrops fetalis also may resolve spontaneously, but intrauterine blood transfusions have been used with apparent success.

343 SMALLPOX, MONKEYPOX, AND OTHER POXVIRUS INFECTIONS

BRETT W. PETERSEN AND INGER K. DAMON

DEFINITION

Human illness caused by a poxvirus is characterized by a cutaneous manifestation; illness may be localized or systemic, depending on the particular poxvirus and the route of introduction. DNA-based assays, including polymerase chain reaction (PCR) and DNA sequencing, are the most precise methods for identification and differentiation of poxvirus genera, species, strains, and variants. The guanosine plus cytosine content of orthopoxviruses, yatapoxviruses, molluscum contagiosum virus, and parapoxviruses is approximately 33%, 32%, 60%, and 63%, respectively.

The Pathogens

All poxviruses described in this chapter (Table 343-1) belong to the family Poxviridae, subfamily Chordopoxvirinae.

EPIDEMIOLOGY

Recognition of the epidemiologic characteristics of poxvirus diseases is valuable in assessing the potential etiologic agent of a particular suspected poxvirus lesion. Knowledge of zoonotic reservoirs, geographic localizations, and capacity for epidemic transmission is critical for clinical assessment and control measures. All human poxvirus infections are zoonotic in nature, with the exception of molluscum contagiosum and variola, which are solely human pathogens. Transmission of virus to humans and to animals is through direct contact with lesions, by fomites, or by inhalation of respiratory droplets.

Parapoxvirus and molluscipoxvirus infections are endemic worldwide; orthopoxvirus and yatapoxvirus infections are geographically restricted, probably by the distribution of competent reservoir hosts. Variola virus (the causative agent of smallpox, a disease declared eradicated in 1980)[1] is the only poxvirus required to be reported to public health systems under the International Health Regulations. In addition to variola virus, Congo Basin clade monkeypox viruses are considered to be select agents by the U.S. government; they must be reported and appropriately handled if discovered and if samples are maintained in the United States. Furthermore, because the availability of laboratory diagnostic testing is limited in many parts of the world, the true incidence and prevalence of poxvirus infections are uncertain.

TABLE 343-1 TAXONOMY OF POXVIRUSES KNOWN TO INFECT HUMANS

GENUS	SPECIES
Orthopoxvirus	Variola virus, vaccinia virus, cowpox virus, monkeypox virus, Akhmeta virus, and Alaskapox virus
Parapoxvirus	Orf virus, milker's node virus, bovine papular stomatitis virus, sealpox virus
Yatapoxvirus	Tanapox virus (Yaba-like disease virus), Yaba monkey tumor virus
Molluscipoxvirus	Molluscum contagiosum virus

Orthopoxvirus

Smallpox

The epidemiology of smallpox, caused by *Orthopoxvirus variola*, is understood through detailed studies conducted during the end of the eradication campaign. Interhuman transmission of variola virus generally occurred through the inhalation of large airborne respiratory droplets of infectious virus. Transmission usually required prolonged face-to-face or other close contact, although airborne transmission over longer distances had been reported.[2] Transmission by fomites or contact with infectious material from the rash also occurred. Aggregate data, collected during the smallpox eradication campaign, suggest a secondary attack rate of about 60% in unvaccinated close or household contacts and a secondary attack rate of about 4% in previously vaccinated close or household contacts. Severity of disease correlated with burden of rash and was also more severe in children and pregnant women. Variola alastrim minor, a variant of variola, had similar human-to-human disease transmission characteristics.

Vaccinia

Vaccinia is the live virus contained in preparations of the smallpox vaccines used to eradicate smallpox. In the United States, the vaccine is recommended for laboratory personnel who use replication-competent orthopoxviruses and for selected military personnel. Contacts of vaccinees occasionally develop vaccinia infections. Vaccinia viruses may have descended from horsepox virus. Vaccinia variants include buffalopox from contact with infected animals in India and vaccinia viruses in dairy cattle workers in Brazil and Colombia.[3]

Monkeypox

Monkeypox has a more complex epidemiology. The virus is zoonotic, and two genetically discrete virus clades have been described, each with apparent distinct clinical and epidemiologic parameters. In central and western Africa, the seroprevalence of anti-orthopoxvirus antibodies in unvaccinated individuals is about 20 to 25%.[4]

In the original outbreak in the Democratic Republic of Congo, the secondary attack rate in unvaccinated contacts of monkeypox cases was calculated to be about 9%. Previous smallpox vaccination (administered 3 to 19 years prior) appeared to be 85% protective against acquisition of the disease among contacts and also ameliorated the severity of disease. Overall, most identified cases acquire disease from presumed animal exposure, and about 30% of cases were ascribed to person-to-person transmission. In more recent outbreaks, however, data suggest that 50 to 90% of infections may be transmitted from human to human, with these higher rates thought to be related to the cessation of smallpox vaccination programs after that disease was eliminated.

Among primary cases, recent close zoonotic contact—through hunting, skinning, killing, cooking, or playing with carcasses—was identified with *Cercopithecus, Colobus*, and *Cercocebus* (primate); *Cricetomys* (terrestrial rodent); and *Funisciurus* and *Heliosciurus* (squirrels). The prevailing hypothesis is that one or more squirrel or rodent species is the probable reservoir of disease.

Monkeypox virus was introduced to the United States in 2003 through a consignment of animals from the West African country of Ghana. The U.S. cases had a less pronounced rash and a less severe illness, with no mortality or human-to-human transmission. These clinical data plus genomic data suggest at least two populations or clades of monkeypox virus. The apparent decreased pathogenicity and transmissibility of West African clade monkeypox virus infection led, in part, to its declassification as a U.S. select agent in 2013. An increasing number of human monkeypox cases were identified in West Africa in 2017, and human monkeypox cases subsequently were identified in the United States, United Kingdom, Israel, and Singapore among returning travelers from Nigeria.[5] More recently, monkeypox spread widely in the United States[6] and throughout the world, initially in men who have sex with men[7] but subsequently in heterosexual contacts, nonsexual contacts, and children. In the United States, cases peaked in August 2022 and eventually exceeded 30,000 cases, with about 40 deaths. Worldwide, about 90,000 cases have been reported.

In the United States, cases peaked in August 2022 and eventually exceeded 30,000 cases, with about 40 deaths. Worldwide, about 90,000 cases have been reported.

ABSTRACT

Human poxvirus infections produce both localized and systemic cutaneous manifestations. Orthopoxvirus variola, the causative agent of smallpox, is the most well-known virus in the family and caused untold deaths before being declared eradicated in 1980. It produced a systemic febrile rash illness with centrifugally distributed characteristic pustules that commonly appeared on the palms and soles. Monkeypox produces a similar clinical syndrome that is distinguished by pronounced lymphadenopathy. Vaccinia virus, which is the virus used for smallpox vaccines, produces a self-limited pustular lesion in humans. Cowpox virus infections present similarly to vaccinia virus infections in humans; both can be acquired through zoonotic transmission and cause severe disease in persons who are immunosuppressed or have skin conditions such as atopic dermatitis. Parapoxviruses (including orf virus, pseudocowpox virus, and bovine papular stomatitis virus) generally cause singular nodular lesions, which can persist for weeks after infection, after contact with ruminants (commonly cattle, sheep, or goats). Molluscum contagiosum causes smooth, dome-shaped, pearly or flesh-colored skin nodules that are often umbilicated. The clinical diagnosis of poxvirus infections can often be made based on the presentation of the disease in combination with epidemiologic characteristics. Laboratory confirmation can usually be achieved using polymerase chain reaction assays. Smallpox vaccine can prevent orthopoxvirus disease because of the development of cross-protective antibodies elicited by infection with a member of the *Orthopoxvirus* genus. Additionally, treatment with antiviral agents such as tecovirimat is available.

KEYWORDS

smallpox
monkeypox
vaccinia virus
cowpox
molluscum contagiosum
poxvirus

Cowpox

Cowpox virus is a zoonosis that is found in Europe and Asia and is maintained in rodents; in Britain, the reservoirs are bank voles and wood mice. The domestic cat is a common source of human infection. Most cases occur between July and October, with only occasional cases between January and June. In Europe, outbreaks in pet rats or feeder rats have been a source of transmission to humans. Cowpox virus also is prevalent in European zoos, where cheetahs, lions, anteaters, rhinoceros, elephants, and okapi have occasionally transmitted infection to animal handlers. No case of bovine cowpox has been detected since 1976, but two cases of a novel orthopoxvirus infection, the Akhmeta virus, were reported in 2013 in the country of Georgia in men who were exposed to ill cows. Alaskapox virus, which is a novel orthopoxvirus infection with a clinical presentation similar to cowpox, has been identified in four patients in Alaska, with wild small mammals living in peri-domestic areas as the likely source.

Parapoxvirus

Human infection with parapoxviruses such as orf[8] is an occupational hazard of farmworkers, abattoir workers, veterinary surgeons, students, and persons who participate in animal slaughter associated with religious observances. It is most common in the lambing and calving seasons and among sheep workers. A novel poxvirus with 88% similarity to *Parapoxvirus* viruses was reported in one patient in Tennessee and one in Missouri, both of whom had regular contact with horses.

Factors responsible for ongoing transmission have been attributed both to the environmental stability of orf virus in scab material and to the manifestation of chronic infections in some animals. A new parapoxvirus has been identified in deer hunters found to have cutaneous lesions after hunting and field-dressing deer.

Molluscipoxvirus

Molluscum contagiosum virus occurs worldwide and parallels cases of acquired immunodeficiency syndrome (AIDS). The disease appears to be sexually transmitted, and genital lesions are more common than lesions elsewhere on the body. Other modes of transmission are associated with mild skin trauma such as abrasions, direct contact with a lesion, and fomites (e.g., shared towels). However, children in daycare or school situations may transmit the disease to other children. Secondary spread may occur by autoinoculation (excoriation of primary lesions and spread to areas of normal skin) as well as by shaving. No known animal reservoir exists.

Yatapoxvirus

Tanapox virus, which is restricted to Africa, principally to Kenya and the Democratic Republic of Congo, probably has a simian reservoir. Direct primate-to-human transmission through a break in skin has rarely been described in animal handlers, but an insect or arthropod intermediary may be involved in the transmission of tanapox virus to humans. No human-to-human transmission has been reported. Yaba monkey tumor virus causes localized infections after contact with infected primate lesions. Little is known about the epidemiology of this virus.

PATHOBIOLOGY

Smallpox

The majority of smallpox infections were initiated by inhalation of respiratory droplets and implantation of virus on the oropharyngeal and respiratory mucosa. No primary localized site of infection was evident if the route of exposure was by inhalation. Disease could also be introduced through suspensions of virus obtained from scabs of infected patients. Transmission by fomites, such as soiled clothing or bed linens, was infrequently reported.

After entry, the virus moves to local lymph nodes and then disseminates to the reticuloendothelial system to replicate further. At this time, the individual is asymptomatic. In 10 to 14 days, secondary viremia occurs and heralds the prodrome of symptomatic illness. During this time, the virus seeds the oropharynx and epidermis. The absence of a keratinized structure in the mucosa of the oropharynx leads to ulceration and release of virus in saliva; the virus replicates in the epidermis to cause the characteristic macular, papular, vesicular, and pustular eruptions of smallpox.

In humans, the viral lesions characteristic of illness primarily develop in the epidermis, where the cells of the Malpighian layer swell and vacuolate to undergo ballooning degeneration. The cytoplasm continues to enlarge, nuclear material is lost, and the coalescence of vacuoles through cell rupture creates reticulating degeneration of the middle and upper layers of the stratum spinosum. In the next stages, the vesicle is formed. High titers of virus are found within the lesions. In mucosal surfaces, the absence of a horny layer allows the necrosis caused by proliferation of virus within the epithelium to create ulcers and leads to liberation of large quantities of virus into the oropharynx. Mild pathologic changes are seen in the lungs.

CLINICAL MANIFESTATIONS

Orthopoxvirus

Smallpox

Four main clinical types of variola can be subgrouped as: *ordinary smallpox* (about 90% of cases), which produced viremia, fever, prostration, and rash; *(vaccine) modified smallpox* (5% of cases), which produced a mild prodrome with few skin lesions in previously vaccinated people and had a mortality rate well below 10%; *flat smallpox* (5% of hospitalized cases), which produced slowly developing lesions that were difficult to ascertain because they appeared flush with the (edematous) skin at the vesicular stage and was almost always fatal; and *hemorrhagic smallpox* (<1% of cases), which induced bleeding into the skin and the mucous membranes and was invariably fatal.

Naturally acquired variola virus infection is characterized by fever and a distinctive rash, with several different clinical presentations (Table 343-2). An asymptomatic incubation period of 10 to 14 days (range: 7 to 17) was followed by a fever that quickly rose to about 103° F (38° to 40° C), sometimes with dermal petechiae. Associated constitutional symptoms included backache, headache, vomiting, and prostration. Within a day or two after incubation, a systemic rash with a characteristic centrifugal distribution (i.e., lesions present in greater numbers on the oral mucosa, face, and extremities than on the trunk) appeared. The fever typically abated as the rash developed. Lesions commonly appeared on the palms and soles. The rash lesions were initially macular and then advanced to the papular stage, at which point they enlarged and progressed to a vesicle by day 4 or 5 and a pustule by day 7. When lesions became pustular, the fever typically returned. Lesions became encrusted and scabbed by day 14 and then sloughed off. Skin lesions in the vesicular and pustular stages were deep-seated and in the same stage of development in any one area of the body (Fig. 343-1). The ordinary disease type was subgrouped into three categories based on the extent of rash on the face and the body: confluent, semiconfluent, and discrete. In *ordinary confluent disease*, no area of skin was visible between vesiculopustular rash lesions on the trunk or the face. In *ordinary semiconfluent* and *discrete disease*, patches of normal skin were visible between rash lesions on the trunk and face, respectively. Less severe manifestations (modified smallpox or variola sine eruptione) occurred in both unvaccinated and, more commonly, vaccinated individuals.

In flat smallpox, illness was heralded by the abrupt onset of fever with temperatures of 38.3° to 38.9° C and the appearance of the rash after 3 to 4 days. The oral enanthem was often confluent; rectal mucosal membranes also could be sloughed. At the papulovesicular stage of disease, lesions appeared as small indentations (day 6) with a hemorrhagic base surrounded by an erythematous ring. By day 7 or 8, the lesions appeared flat. Bullous lesions that would slough were reported. Fever persisted throughout the disease course,

TABLE 343-2 WORLD HEALTH ORGANIZATION (WHO) SMALLPOX TYPES

WHO SMALLPOX TYPE	CLINICAL DEFINITION
Variola sine eruptione	Fever, no rash
Modified	Like ordinary, with an accelerated course
Ordinary discrete	Fever, rash; areas of normal skin between pustules, even on the face
Ordinary semiconfluent	Fever, rash; pustules confluent on the face, discrete elsewhere
Ordinary confluent	Fever, rash; pustules confluent on the face and forearms
Flat	Fever, erythema, and edema of the skin; vesicles soft, flat, and bullous
Hemorrhagic, early	Fever (persistent), hemorrhages and petechiae, purpuric rash at illness onset
Hemorrhagic, late	Fever (persistent), rash, hemorrhage into the base of vesicles late in illness

FIGURE 343-1. Pustular lesions of smallpox and beginning of scarring on the face and upper part of the torso. (From the Centers for Disease Control and Prevention Public Health Image Library, ID #: 7055. Photograph by Stan Foster.)

and respiratory complications were often observed by day 7 or 8 of illness. Thrombocytopenia, neutropenia, and lymphocytosis were reported.

In hemorrhagic forms of smallpox, illness began with fever and typical prodromal symptoms, but the fever never abated. Early after the onset of fever, petechiae and purpuric rashes became apparent; subconjunctival hemorrhages, hematuria, and vaginal bleeding were also seen. Patients usually died by day 6 of illness, well before any classic vesiculopustular rash was evident, but some patients developed typical maculopapular lesions with a hemorrhagic base, bleeding in the mucous membranes, and profound thrombocytopenia before dying between days 8 and 10 of illness.

Alastrim variola minor infection results in a discrete type of the ordinary form, with a typical febrile prodrome and rash. Individuals with this form of disease are not nearly as sick as individuals with variola major infection. Previous vaccination was not necessarily protective against the hemorrhagic forms of disease; however, it seemed to be protective against flat forms of disease.

Vaccinia

Post-Vaccination Vaccinia

For laboratory personnel working with orthopoxviruses, health care personnel, and military personnel in the United States, the smallpox vaccination regimen (with vaccinia or a replication-competent smallpox) results in purposeful infection. Most commonly, the infection progresses through a standard course of events from vesicle to pustule. Major complications include progressive vaccinia, eczema vaccinatum, generalized vaccinia, post-vaccinial encephalitis, accidental infection, and myopericarditis.

Progressive vaccinia, which is a rare and often fatal vaccine complication in persons with severe deficiencies in cellular immunity, occurs in about 1 per 1 million vaccines. Progressive vaccinia is characterized by frequently painless growth and spread of the vaccine virus beyond the inoculation site, often leading to necrosis and sometimes metastases to other body sites. The possibility of progressive vaccinia should be considered if vaccinia virus infection continues to progress and expand without apparent healing more than 15 days after vaccination.

Eczema vaccinatum can occur in people with a history of atopic dermatitis (eczema), irrespective of its severity or activity, owing to local spread or dissemination from the primary vaccination site or contact with the unscabbed vaccination site of another person. A localized or generalized papular, vesicular, or pustular rash can develop anywhere on the body or be localized to previous eczematous lesions. Systemic illness with fever, malaise, and lymphadenopathy may occur. In the 1968 national U.S. surveillance of smallpox vaccination, there were 66 cases (no deaths) of eczema vaccinatum among 14.5 million vaccinees (4.6 cases/million) and 60 cases (1 death) among their several million contacts.

FIGURE 343-2. Vaccinia autoinoculation of an eye. (From the Centers for Disease Control and Prevention Public Health Image Library, ID #: 3322.)

Generalized vaccinia, which describes the vesicular rash that develops after vaccination, is estimated to occur in about 242 of every million primary vaccinations. Generalized vaccinia is believed to represent the end product of viremic spread of virus, and no predisposing factors have been identified.

Post-vaccination encephalomyelitis is a rare but serious complication that usually occurs only in primary vaccinees. Patients have variably displayed clinical and diagnostic features suggestive of a postimmunization demyelinating encephalomyelitis or direct viral invasion of the nervous system. This postvaccination reaction typically occurs 11 to 15 days after vaccination. Symptoms include fever, headache, vomiting, confusion, delirium, disorientation, restlessness, drowsiness or lethargy, seizures, and coma. Cerebrospinal fluid can demonstrate elevated pressure but generally has a normal cell count and chemistry profile. The diagnosis is one of exclusion, and no specific tests are available to confirm it.

Accidental infection occurs when virus from the vaccination site is transferred to another site or to another person through intimate skin contact. This complication generally occurs with primary vaccinees rather than revaccinees. Accidental self-inoculation, which most commonly occurs on the face, mouth, lips, or genitalia, is not usually serious and requires no specific treatment. Inoculation of the eye or eyelid is more serious and can be sight threatening if it is not evaluated and treated appropriately (Fig. 343-2). Between 1963 and 1968, ocular vaccinia was observed in 343 persons, including 22 who had evidence of corneal involvement and 11 who experienced permanent defects.

Bovine-Associated Vaccinia

With bovine-associated vaccinia virus infections (e.g., buffalopox viruses in India and vaccinia viruses in Brazil and Colombia), up to 10 lesions have been described on the hands or arms of exposed farmworkers. Fever, lymphadenopathy, backache, and fatigue are also associated symptoms. Transmission is believed to occur by unprotected contact with active lesions present on animal teats and udders. Interhuman transmission of bovine-associated vaccinia virus to family members has been reported to occur through contact with lesion exudates.

Monkeypox

After an incubation period of 7 to 17 days (mean: 12 days), a prodrome of fever, headache, backache, and fatigue begins.[9] Lesions similar to smallpox evolve in the same stage in any one part of the body from macules, papules, and vesicles to pustules, and then they crust and scar (Fig. 343-3).[10] After resolution of the rash, hypopigmentation is followed by hyperpigmentation of the scarred lesions. Pronounced cervical, postauricular, submandibular, and inguinal lymphadenopathy clinically distinguishes monkeypox from smallpox. Subclinical infection may occur in 25 to 30% of close contacts of monkeypox patients. Systemic complications can include severe pharyngitis that limits oral intake, soft-tissue superinfection, and severe anorectal pain.[11] Neurologic manifestations can include headache, mood disturbances, and even encephalitis.[12]

Cowpox

Cowpox lesions are generally restricted to the hands and face, and most patients (about 70%) have only one lesion. Multiple lesions may be caused by multiple primary inoculations, by autoinoculation, and very infrequently

FIGURE 343-3. **Rash of monkeypox of the head (A) and extremities (B) in a 7-year-old girl in central Zaire.** (From Peters W, Pasvol G. *Tropical Medicine and Parasitology*. 5th ed. New York: Mosby; 2002:238.)

by lymphatic or viremic spread. The cowpox lesion passes through macular, papular, vesicular, and pustular stages before forming a hard black crust. The lesion is generally very painful, and erythema and edema are common at the late vesicular and pustular stages. Patients usually have lymphadenitis, fever, and general malaise. About 30% of patients may be hospitalized. Most patients take 6 to 8 weeks to recover, but up to 12 weeks may be required. Scarring is usually permanent.

Parapoxvirus

Lesions, such as from the orf virus, start as erythematous papules and progress in 1 to 2 weeks to target lesions with a red center surrounded by a white halo and an outer inflamed halo. Lesions then progress to a nodular and then a papillomatous stage, which often has a "weeping" surface. In some patients, lesions may enlarge and persist for weeks before resolving by a crusting stage, which also may persist for weeks. Very large granulomatous lesions may occasionally require surgical débridement or removal.

Most patients have only one lesion, but multiple primary lesions may develop. Systemic reaction is relatively uncommon, and the lesion is often not particularly painful. Lymphadenopathy is present in some patients, and lymphangitis is relatively uncommon. Erythema multiforme (Chapter 407) can develop in up to one third of patients.

Molluscum Contagiosum Virus

The characteristic lesion begins as a small papule and, when mature, is a discrete, 2- to 5-mm-diameter, smooth, dome-shaped, pearly or flesh-colored nodule that is often umbilicated (see Fig. 407-9 in Chapter 407).[13] A cheesy, off-white or yellowish material is easily expressed from lesions. Most patients have 1 to 20 lesions, but hundreds of lesions may occasionally be present. Because of multiple simultaneous infections or mechanical spread, the lesions may become confluent along the line of a scratch, and satellite lesions are sometimes seen.

In adults, lesions tend to occur on the trunk, pubic area, and thighs, but infection can be transmitted to other areas by autoinoculation. In men infected with human immunodeficiency virus (HIV), molluscum lesions can occur along the beard line and can result in ocular involvement.

Individual lesions persist for about 2 months, but the disease usually persists for 6 to 9 months. Individuals with impaired cell-mediated immunity, including persons with HIV infection, tend to have more severe and prolonged infection.

Yatapoxvirus

Tanapox infection begins with a short febrile (38° to 39° C) illness that persists for 2 to 4 days and is sometimes accompanied by headache, backache, or prostration. The eruption of a lesion is frequently heralded by pruritus at the site of the outbreak. The lesion appears as a hyperpigmented macule, which often has central elevation and evolves to a papule with palpable induration. About 80% of patients have a solitary nodule, but as many as 10 lesions can occur. Most lesions (about 70%) occur on the lower extremities, and the fewest occur on the face and areas normally covered by clothing.

Fever and systemic symptoms wane as the lesion erupts. The papule then becomes more "pocklike" but contains no fluid; umbilication or a pseudocrust may develop. Typically, the papule evolves into a firm, deep-seated, elevated nodule. At the end of the first week, the lesion is surrounded by erythema and indurated skin, and regional lymphangitis is common. Lesions then either ulcerate or become larger nodules (up to 2 cm in diameter) within about 2 weeks, after which the local inflammatory response wanes and the lesions began to granulate. Resolution of lesions occurs within 6 weeks. Infection appears to confer lifelong immunity.

DIAGNOSIS

Smallpox and Other Orthopoxviruses

If smallpox is suspected, clinicians should follow a standardized protocol (https://www.cdc.gov/smallpox/clinicians/algorithm-protocol.html) because of the possibility of bioterrorism (Chapter 19) as well as the risk to laboratory personnel (https://www.cdc.gov/smallpox/lab-personnel/laboratory-procedures/rash-testing.html). Unlike smallpox, chickenpox (Chapter 346) produces a centripetally distributed rash and rarely appears on the palms and soles; the lesions are superficial in nature, and lesions in different developmental stages may be present in the same area of the body. Other diseases and conditions that could be confused with vesicular-stage smallpox include monkeypox, generalized vaccinia, disseminated herpes zoster or herpes simplex virus infection (Chapters 345 and 346), drug reactions (eruptions), erythema multiforme (Chapter 407), enteroviral infections (Chapter 349), scabies (Chapter 98), insect bites, impetigo (Chapter 408), and molluscum contagiosum.[14] Diseases confused with hemorrhagic smallpox included acute leukemia (Chapter 168), meningococcemia (Chapter 274), and idiopathic thrombocytopenic purpura (Chapter 158).

Nucleic acid–based tests and polymerase chain reaction (PCR) assays are the first approach to the diagnosis of orthopoxvirus infections. If the diagnosis of smallpox is being considered, viral culture requires a biosafety level 4 (BSL-4) containment facility that is sanctioned to use variola virus.

Parapoxvirus

The differential diagnosis of parapoxvirus lesions can include ecthyma gangrenosum as a result of a *Pseudomonas aeruginosa* infection (Chapter 282), vaccinia or cowpox infection, cutaneous anthrax (Chapter 272), erysipeloid (Chapter 272), tularemia (Chapter 287), and tumor. Farmworkers recognize the infection and tend not to seek medical attention for routine cases, so about 45% of reported cases may have no known contact with infected animals, and the clinical diagnosis of such cases may be difficult. Virions with the characteristic morphology of parapoxviruses are usually seen in lesion extracts on electron microscopy, thereby providing a rapid, certain diagnosis of the genus.

Molluscum Contagiosum Virus

The clinical appearance of molluscum lesions usually is sufficiently characteristic to permit a clinical diagnosis.

Yatapoxvirus

The limited geographic distribution of tanapox virus and the patient's travel history help with the diagnosis of tanapox infection. Unique clinical features that differentiate tanapox from other orthopoxvirus infections are the nodular nature of the rash lesion, the paucity of lesions, the benign disease course, and the protracted resolution of the rash. Nucleic acid testing of material from the lesions is diagnostic.

TREATMENT AND PREVENTION

Orthopoxvirus

Vaccination with smallpox vaccine is the mainstay for prevention of orthopoxvirus infection and was the primary method used to eradicate smallpox. Stockpiles of vaccine are available should smallpox recur, and guidance is available for their use in an emergency (https://www.cdc.gov/mmwr/preview/mmwrhtml/rr6402a1.htm). A replication-deficient smallpox vaccine, which has excellent immunogenicity with fewer adverse effects than prior vaccines, is licensed to prevent smallpox and monkeypox.[15] In the United States, it is being recommended for persons at risk of exposure to orthopoxviruses, including monkeypox.[16]

Early administration of vaccinia immune globulin (VIG) may reduce the mortality of eczema vaccinatum from 30 to 40% to 7%, and VIG may also be useful for other complications (e.g., progressive vaccinia, severe generalized vaccinia, or contact infection) of vaccinia (smallpox) vaccine administration and for other orthopoxvirus infections. However, VIG alone has no clear benefit for treatment of smallpox infection itself.

Tecovirimat is an effective small-molecule antiviral in animal models of systemic orthopoxvirus infection.[17] It is part of the U.S. Strategic National Stockpile and was licensed by the FDA for treatment of human smallpox disease. Brincidofovir is also licensed by the U.S. FDA for treatment of smallpox based on data in animals.[18] Tecovirimat and brincidofovir also have been used successfully to treat severe human cases of other orthopoxvirus infections, including monkeypox,[19] under expert supervision.

Antiviral compounds (Chapter 328) with in vitro and in vivo activity against poxviruses include specifically 5-iodo-2′-deoxyuridine, adenine arabinoside, and trifluorothymidine. Because of their systemic toxicity, these compounds have been used topically for the treatment of orthopoxvirus ocular infections. In vitro, cidofovir is active against cowpox, vaccinia, monkeypox, and variola. Cidofovir has known renal toxicity and is administered with hydration and probenecid.

Parapoxvirus

Treatment options are limited. Anecdotal reports have described the use of topical and intralesional cidofovir, and other options may be topical formulations of interferon-modulating compounds such as imiquimod.

Molluscum Contagiosum Virus

Molluscum contagiosum infection is benign, recovery is usually spontaneous, and no medical therapy has been consistently effective.[A1] However, treatment may be sought for cosmetic reasons, particularly for facial or multiple lesions. Cryotherapy and mechanical curettage are the most successful options.[A2] Typical chemical treatments such as podophyllin or podofilox, salicylic acid with lactic acid nitric oxide–releasing gel,[20] and 3% cidofovir antiviral cream or suspension may be helpful. Irritation has been a side effect of many of the chemical treatments. Covering of lesions and the use of proper hand hygiene after contact with lesions should prevent transmission in most situations. For individuals with AIDS and molluscum, highly active antiretroviral therapy with a resulting improvement in the $CD4^+$ cell count appears to be efficacious.

PROGNOSIS

Ordinary smallpox has a variable mortality rate ranging from 10 to 40%, which correlates with the extent and severity of the skin lesions. Flat smallpox and hemorrhagic smallpox are almost universally fatal, whereas modified smallpox in previously vaccinated patients has a mortality rate well below 10%. Variola minor variants have mortality rates of less than 1%. Vaccina virus infections after smallpox vaccination are usually self-limited, but progressive vaccinia in immunocompromised patients has a case fatality rate of about 35%. Monkeypox has a case-fatality rate of approximately 1 to 10% in persons who have not been vaccinated for smallpox, with most fatalities in children younger than age 5 years. Cowpox virus infections usually cause self-limited disease but can be severe and fatal in persons with immunosuppression or certain skin conditions such as atopic dermatitis. Parapoxvirus infections are manifested chiefly by localized symptoms, and the lesions resolve within a month or so in nonimmunocompetent hosts. Molluscum contagiosum infection is benign, usually with a spontaneous recovery, but the infection can persist for months. Yatapoxvirus infections are self-limited, and the illness resolves in the course of a few weeks.

344 PAPILLOMAVIRUS

SEAN T. O'LEARY AND JOHN M. DOUGLAS, JR.

DEFINITION

Human papillomaviruses (HPVs) are a group of small DNA viruses that cause a variety of benign and malignant lesions of the skin and mucous membranes. The most commonly recognized HPV-associated diseases include warts (Chapter 407) at anogenital sites (condyloma acuminatum), other skin surfaces (common wart or verruca vulgaris, as well as flat wart or verruca plana), and the plantar surface of the foot (verruca plantaris). In addition, HPV infection causes squamous intraepithelial lesions, or incipient cancers, of the cervix, also known as cervical intraepithelial neoplasia, and of other anogenital sites. It is considered the etiologic agent of a variety of cancers, especially cervical (Chapter 184), anal (Chapter 131), and oropharyngeal (Chapter 176) cancers.

The Pathogen

HPV is a member of the family Papillomaviridae. Like all papillomaviruses, HPV is nonenveloped, measures 55 nm in diameter, and has a double-stranded circular DNA genome of approximately 7900 base pairs enclosed by an icosahedral capsid. The HPV genome contains three functional regions: early genes (six total—E1, E2, E4, E5, E6, E7), which are expressed soon after infection and control replication, transcription, and cellular proliferation; late genes (two total—L1, L2), which are expressed in later stages of infection and encode the structural capsid proteins; and the long control region, which contains regulatory sequences that control the replication and transcription of early and late genes. Papillomaviruses complete their life cycle only in terminally differentiated epithelial cells and thus cannot be grown in monolayer cell cultures. Papillomavirus taxonomy is based on a genotyping system involving the use of DNA sequence relatedness of the gene encoding L1, the major capsid protein, with different types defined as having less than 90% homology.

Papillomaviruses are classified taxonomically by genus (Greek letters) and species (numbered), each containing one or more types. Most HPV types are included in three large genera: alpha (primarily mucosal or genital types), beta, and gamma (both of which cause cutaneous lesions). Currently, over 200 types of HPV have been identified, over 40 of which infect genital skin and mucosa [http://pave.niaid.nih.gov/#explore/reference_genomes/human_genomes]. Of the genital types, approximately 15 are considered high risk because they are associated with high-grade squamous intraepithelial lesions and cancers of the cervix, anus, penis, vulva, vagina, and oropharynx, whereas others are considered low risk because they are largely associated with genital warts and low-grade squamous intraepithelial lesions.

EPIDEMIOLOGY

HPV infections are primarily transmitted by direct contact of skin or mucous membranes with an infected lesion. Genital HPV infection is typically contracted through sexual intercourse, although nonpenetrative genital contact, oral-genital contact, and manual-genital contact are also possible routes of transmission. In addition, genital HPV infection can be transmitted to the mouth and upper respiratory tract perinatally from infected mothers to newborns. For

Yatapoxvirus

The limited geographic distribution of tanapox virus and the patient's travel history help with the diagnosis of tanapox infection. Unique clinical features that differentiate tanapox from other orthopoxvirus infections are the nodular nature of the rash lesion, the paucity of lesions, the benign disease course, and the protracted resolution of the rash. Nucleic acid testing of material from the lesions is diagnostic.

TREATMENT AND PREVENTION

Orthopoxvirus

Vaccination with smallpox vaccine is the mainstay for prevention of orthopoxvirus infection and was the primary method used to eradicate smallpox. Stockpiles of vaccine are available should smallpox recur, and guidance is available for their use in an emergency (https://www.cdc.gov/mmwr/preview/mmwrhtml/rr6402a1.htm). A replication-deficient smallpox vaccine, which has excellent immunogenicity with fewer adverse effects than prior vaccines, is licensed to prevent smallpox and monkeypox.[15] In the United States, it is being recommended for persons at risk of exposure to orthopoxviruses, including monkeypox.[16]

Early administration of vaccinia immune globulin (VIG) may reduce the mortality of eczema vaccinatum from 30 to 40% to 7%, and VIG may also be useful for other complications (e.g., progressive vaccinia, severe generalized vaccinia, or contact infection) of vaccinia (smallpox) vaccine administration and for other orthopoxvirus infections. However, VIG alone has no clear benefit for treatment of smallpox infection itself.

Tecovirimat is an effective small-molecule antiviral in animal models of systemic orthopoxvirus infection.[17] It is part of the U.S. Strategic National Stockpile and was licensed by the FDA for treatment of human smallpox disease. Brincidofovir is also licensed by the U.S. FDA for treatment of smallpox based on data in animals.[18] Tecovirimat and brincidofovir also have been used successfully to treat severe human cases of other orthopoxvirus infections, including monkeypox,[19] under expert supervision.

Antiviral compounds (Chapter 328) with in vitro and in vivo activity against poxviruses include specifically 5-iodo-2′-deoxyuridine, adenine arabinoside, and trifluorothymidine. Because of their systemic toxicity, these compounds have been used topically for the treatment of orthopoxvirus ocular infections. In vitro, cidofovir is active against cowpox, vaccinia, monkeypox, and variola. Cidofovir has known renal toxicity and is administered with hydration and probenecid.

Parapoxvirus

Treatment options are limited. Anecdotal reports have described the use of topical and intralesional cidofovir, and other options may be topical formulations of interferon-modulating compounds such as imiquimod.

Molluscum Contagiosum Virus

Molluscum contagiosum infection is benign, recovery is usually spontaneous, and no medical therapy has been consistently effective.[A1] However, treatment may be sought for cosmetic reasons, particularly for facial or multiple lesions. Cryotherapy and mechanical curettage are the most successful options.[A2] Typical chemical treatments such as podophyllin or podofilox, salicylic acid with lactic acid nitric oxide–releasing gel,[20] and 3% cidofovir antiviral cream or suspension may be helpful. Irritation has been a side effect of many of the chemical treatments. Covering of lesions and the use of proper hand hygiene after contact with lesions should prevent transmission in most situations. For individuals with AIDS and molluscum, highly active antiretroviral therapy with a resulting improvement in the $CD4^+$ cell count appears to be efficacious.

PROGNOSIS

Ordinary smallpox has a variable mortality rate ranging from 10 to 40%, which correlates with the extent and severity of the skin lesions. Flat smallpox and hemorrhagic smallpox are almost universally fatal, whereas modified smallpox in previously vaccinated patients has a mortality rate well below 10%. Variola minor variants have mortality rates of less than 1%. Vaccina virus infections after smallpox vaccination are usually self-limited, but progressive vaccinia in immunocompromised patients has a case fatality rate of about 35%. Monkeypox has a case-fatality rate of approximately 1 to 10% in persons who have not been vaccinated for smallpox, with most fatalities in children younger than age 5 years. Cowpox virus infections usually cause self-limited disease but can be severe and fatal in persons with immunosuppression or certain skin conditions such as atopic dermatitis. Parapoxvirus infections are manifested chiefly by localized symptoms, and the lesions resolve within a month or so in nonimmunocompetent hosts. Molluscum contagiosum infection is benign, usually with a spontaneous recovery, but the infection can persist for months. Yatapoxvirus infections are self-limited, and the illness resolves in the course of a few weeks.

344 PAPILLOMAVIRUS

SEAN T. O'LEARY AND JOHN M. DOUGLAS, JR.

DEFINITION

Human papillomaviruses (HPVs) are a group of small DNA viruses that cause a variety of benign and malignant lesions of the skin and mucous membranes. The most commonly recognized HPV-associated diseases include warts (Chapter 407) at anogenital sites (condyloma acuminatum), other skin surfaces (common wart or verruca vulgaris, as well as flat wart or verruca plana), and the plantar surface of the foot (verruca plantaris). In addition, HPV infection causes squamous intraepithelial lesions, or incipient cancers, of the cervix, also known as cervical intraepithelial neoplasia, and of other anogenital sites. It is considered the etiologic agent of a variety of cancers, especially cervical (Chapter 184), anal (Chapter 131), and oropharyngeal (Chapter 176) cancers.

The Pathogen

HPV is a member of the family Papillomaviridae. Like all papillomaviruses, HPV is nonenveloped, measures 55 nm in diameter, and has a double-stranded circular DNA genome of approximately 7900 base pairs enclosed by an icosahedral capsid. The HPV genome contains three functional regions: early genes (six total—E1, E2, E4, E5, E6, E7), which are expressed soon after infection and control replication, transcription, and cellular proliferation; late genes (two total—L1, L2), which are expressed in later stages of infection and encode the structural capsid proteins; and the long control region, which contains regulatory sequences that control the replication and transcription of early and late genes. Papillomaviruses complete their life cycle only in terminally differentiated epithelial cells and thus cannot be grown in monolayer cell cultures. Papillomavirus taxonomy is based on a genotyping system involving the use of DNA sequence relatedness of the gene encoding L1, the major capsid protein, with different types defined as having less than 90% homology.

Papillomaviruses are classified taxonomically by genus (Greek letters) and species (numbered), each containing one or more types. Most HPV types are included in three large genera: alpha (primarily mucosal or genital types), beta, and gamma (both of which cause cutaneous lesions). Currently, over 200 types of HPV have been identified, over 40 of which infect genital skin and mucosa [http://pave.niaid.nih.gov/#explore/reference_genomes/human_genomes]. Of the genital types, approximately 15 are considered high risk because they are associated with high-grade squamous intraepithelial lesions and cancers of the cervix, anus, penis, vulva, vagina, and oropharynx, whereas others are considered low risk because they are largely associated with genital warts and low-grade squamous intraepithelial lesions.

EPIDEMIOLOGY

HPV infections are primarily transmitted by direct contact of skin or mucous membranes with an infected lesion. Genital HPV infection is typically contracted through sexual intercourse, although nonpenetrative genital contact, oral-genital contact, and manual-genital contact are also possible routes of transmission. In addition, genital HPV infection can be transmitted to the mouth and upper respiratory tract perinatally from infected mothers to newborns. For

ABSTRACT

Human papillomaviruses (HPVs) are a large group of DNA viruses that typically infect the stratified epithelia of the skin and mucous membranes. They cause tumors ranging from benign to malignant according to the specific oncogenic risk of each viral genotype. The most common benign lesions are cutaneous warts found on the hands and feet, caused predominantly by HPV types 1, 2, and 4; and genital warts, caused by HPV types 6 and 11. HPV-16, -18, and several other genotypes can also infect the anus and lower genital tract causing lesions that can progress to intraepithelial neoplasias, the precursors of squamous cell carcinomas of the cervix, vagina, vulva, penis, and anus. These oncogenic HPVs are also found in some squamous carcinomas of the oropharynx. These infections are transmitted by direct contact and can remain asymptomatic, clear, or cause lesions that often can spontaneously regress. Persistent infection with oncogenic HPVs is the main determinant for progression to cancer. Available treatments that address the disease but not the infection include various chemical and physical destructive methods. Cervical cancer can be effectively prevented by screening using cervical cytology (Pap smear) or HPV DNA. Condoms offer some protection against the transmission of genital HPV infections. An available vaccine directed at nine of the most common genotypes associated with genital warts and cervical cancer has been highly effective in reducing the incidence of genital warts, oropharyngeal infection, and intraepithelial neoplasias of the cervix, vagina, vulva, and anus when administered before the initiation of sexual activity.

intraepithelial neoplasia

nongenital HPV infection, personal skin-to-skin contact also plays a primary role, whereas fomite transmission from moist surfaces is an important source of infection for plantar warts. Both genital and nongenital infection can be transmitted to new sites by autoinoculation.

Recent estimates are that 43 million males and females ages 15 to 59 years in the United States are infected with genital HPV, with about 13 million new infections occurring annually, thereby making genital HPV the most common sexually transmitted infection.[1] Acquisition of infection begins shortly after sexual debut, with risk factors related to probable exposure (e.g., younger age at onset of sexual activity, increased number of recent and lifetime partners, and number of partners of the sex partners), susceptibility (e.g., lack of circumcision for men), and absence of effective prevention (e.g., lack of consistent condom use or immunization). Most infections are asymptomatic and clear without treatment; only 10% are estimated to persist longer than 2 years. The incidence and prevalence of genital HPV infection and genital warts have been declining substantially in countries with successful immunization programs. For example, between 2003 and 2018, the prevalence of infection with the four viral types included in the original quadrivalent vaccine declined by over 80% in vaccinated women under age 25 years. Reductions of over 65% have also been seen in unvaccinated women, thereby indicating some element of indirect or herd protection.[2]

Oral HPV infection is usually asymptomatic, but when symptomatic it takes the appearance of warts or papillomas. Its prevalence in U.S. adults is lower than genital infection—approximately 3 to 7% in women and 10 to 12% in men[3], almost half of which are due to high-risk types. Risk factors for prevalent infection include number of sex partners, age, and smoking. Newly acquired oral oncogenic HPV infections are rare in healthy men, and most infections are cleared within 1 year. As with genital HPV infection, oral HPV infection has declined in the vaccine era, especially among men.[4] Cutaneous HPV infection is most typically recognized as common and plantar warts, especially in children, in whom annual incidence rates of up to 30% have been reported.

All types and manifestations of HPV infection are more common in persons with impaired cell-mediated immunity, such as those infected with human immunodeficiency virus (HIV) or receiving immunosuppressive therapy. HIV-infected persons have higher rates of intra-epithelial neoplasia at various genital and anal sites, as well as higher rates of cervical and anal cancer, although both have declined in the United States in recent years, likely as a result of widespread HIV antiretroviral therapy.[5] Evidence also suggests that genital HPV infection increases susceptibility to HIV infection.

Cervical cancer (Chapter 184) has declined in developed countries since the initiation of cytologic screening programs, although about 14,000 cases and 4300 deaths still occur in the United States annually.[6] Cervical cancer is the fourth most common and lethal cancer in women worldwide, and almost 90% of the 311,000 annual deaths occur in low- and middle-income countries. Considering all anatomic sites, almost 36,000 HPV-associated cancers occur in the United States each year, about 60% among females.[7] Oropharyngeal cancer (Chapter 176) has risen sharply over the past 20 years, particularly among men, and is now the most common HPV-associated cancer in the United States.

PATHOBIOLOGY

HPV infections cause disease by inducing proliferation of the epithelium of the skin and mucous membranes. In benign lesions, such as warts and condylomas, all epithelial layers are involved, except for the basal layer of replicating keratinocytes. The proliferation of the stratum spinosum is called acanthosis, that of the stratum granulosum parakeratosis, and that of the stratum corneum hyperkeratosis. The overall growth is called papillomatosis because it typically occurs mostly above the tissue surface but is also associated with a deepening of the rete ridges of the basement membrane. It is also accompanied by large cells with a hyperchromatic, shrunken nucleus (or nuclei) surrounded by a halo (called koilocytes) in the stratum acanthosum. For the cytopathologist, koilocytosis is the hallmark of HPV infection.

Epidermodysplasia verruciformis is an uncommon autosomal recessive disease with diffuse warts that result from the mutation of one of two adjacent genes, *EVER1/TMC6* and *EVER2/TMC8*, each coding for proteins involved in the transcription factor NF-κB that participates in the control of cell-mediated immunity.

For precancerous or cancerous lesions, dyskaryosis is caused by the proliferation of the basal layer cells, which also exhibit abnormal mitoses. This dyskaryosis progresses by replacing the upper layers of the stratified epithelium, thereby causing increasing grades 1 to 3 of intraepithelial neoplasia, according to how many thirds of the epithelium are involved. Full-thickness involvement defines carcinoma in situ. The breach of the basement membrane indicates invasive cancer. The intraepithelial neoplasias (IN) of the cervix, vagina, vulva, penis, and anus also go by the acronyms of CIN, VAIN, VIN, PIN, and AIN, respectively. For the cervix, low-grade squamous intraepithelial lesion (LSIL) is the equivalent of flat condyloma and CIN1, whereas high-grade squamous intraepithelial lesion (HSIL) regroups CIN2 and 3. To parallel these changes, low- and high-grade cervical intraepithelial neoplasia (LCIN and HCIN, respectively) are now terms also used in histology. The higher the cytologic or histologic grade of neoplasia, the higher the intralesional relative prevalence of high-risk HPV types.

At the cellular level, infection begins in the lowest and least differentiated layer of the epithelium, the basal cells, when they are exposed by microtrauma.[8] Transcription and protein expression are highly coordinated with the level of cellular differentiation. In the basal layer, the viral genome becomes established in the nucleus as an episome that replicates in tandem with cellular replication, thus maintaining a stable copy number of viral genomes. As basal cells migrate up and differentiate in the superficial layers of the epithelium, full vegetative viral DNA replication and expression of structural proteins occur, with assembly of infectious virions in the most superficial layer of the epithelium. Virions are released with the sloughing of dead cells during normal cellular turnover.

Persistent infection with various high-risk types of genital HPV is firmly established as the cause of squamous cell carcinoma and adenocarcinoma of the cervix, and HPV 16 in particular plays a causal role in other anogenital and oropharyngeal squamous cell cancers. There are also associations of beta-HPV types with squamous cell cancer of the skin. HPV DNA can be detected in more than 99% of cervical cancer cases, with 70% of cancers caused by the two most common high-risk types, HPV 16 and 18. The pathogenesis of HPV-induced cancer involves viral integration into the host genome with resulting disruption of the E2 transcription regulatory gene and increased expression of E6 and E7 proteins. These proteins have oncogenic activity and affect cell growth by binding with tumor suppressor proteins, E6 with p53 and E7 with the retinoblastoma tumor suppressor protein, thereby disrupting apoptosis and cell cycle regulation.

The oncogenic risk of HPV varies not only by type, with HPV 16 being the most oncogenic, but also according to variants (i.e., sharing between 95 and 98% of DNA homology) within a given type. A high viral load may also contribute to the risk. Although a persistent infection with a high-risk type is "necessary" for the development of cervical cancer, it is not considered "sufficient" because cancer does not develop in the majority of persistently infected women. Possible cofactors include cigarette smoking, prolonged hormonal contraceptive use, multiparity, micronutrient deficiency, immunodeficiency (e.g., HIV infection), and possibly other infections, (i.e., *Chlamydia trachomatis* and herpes simplex virus type 2). In addition, data supporting a familial risk for cervical cancer point to possible genetic factors, including genes controlling the immune response (e.g., human leukocyte antigens and tumor necrosis factor) and cell cycle (e.g., p53).

The squamous epithelium of the ectocervix and columnar epithelium of the endocervix form a squamo-columnar junction that, from birth through life, recedes towards the endocervix, traveling an area called the transformation zone, where cervical cancers (Chapter 184) arise. Squamo-columnar junctions, but without a transformation zone, also exist in the anus and larynx, and HPV benign or malignant lesions often arise in epithelium that is in close proximity (see Chapter 131 for anal cancer).

The immune response to HPV infection is less robust than for most viral infections. Viral proteins and infectious virions develop in superficial cells with limited contact with the immune system, and there is no cell lysis or viremia to trigger an inflammatory response. In addition, HPV suppresses several components of the immune response, including the interferon pathway and the expression of inflammatory cytokines and the major histocompatibility complex I. Antibody to HPV develops in only an estimated 60% of infected individuals, often as long as 6 to 12 months after infection. In contrast, the dynamics of the immune response are quite different after immunization, with almost 100% seroconversion within several months and antibody levels many-fold higher than those after natural infection. The high prophylactic efficacy of papillomavirus vaccines is due to humoral immunity and the intense production of neutralizing antibodies. Once papillomavirus infection is established, cellular immunity appears to be critical for clearance of infection.

CLINICAL MANIFESTATIONS

The clinical manifestations of HPV infection vary by anatomic site and viral type. About 2% of patients may have both oral and genital infections on initial presentation.[9]

Common warts are exophytic, hyperkeratotic papules that typically occur on the hands but can appear on any skin surface, occasionally including the genital skin; they are most commonly caused by HPV types 1, 2, 4, 27, and 57. Plantar warts, which are caused by similar types of HPV, are hyperkeratotic papules. They may present as deep plantar warts that often are very painful and endophytic in growth. They are typically associated with HPV types 1 or 63. More superficial and painless mosaic warts are typically caused by HPV types 2 or 4. In contrast, flat warts (verruca plana), which are small flat-topped papules that occur more commonly on the face, hands, and legs, are caused by a different group of nongenital HPV types (e.g., types 3, 10, 28, 38, 42, 49, 75, 76).

Epidermodysplasia verruciformis is usually manifested in childhood as diffuse warts that respond poorly to treatment. The diffuse warts of epidermodysplasia verruciformis can be associated with two types of lesions: flat warts caused by the same HPV types as in normal hosts, and scaly tinea versicolor–type lesions caused by epidermodysplasia verruciformis–associated types. The latter are associated with the development of squamous cell cancers in sun-exposed areas in 30 to 70% of persons of age 30 years and older. Similar skin lesions and, rarely, associated skin cancers can develop in other patients with acquired defects in cell-mediated immunity or who are immunosuppressed.

Bowenoid papulosis is defined by the combination of hyperpigmentation, intraepithelial neoplastic histology, and the cytoarchitecture of a condyloma. It can transform into Bowen disease (Chapter 188), which is a squamous carcinoma in situ that occurs most commonly in areas of prior skin damage.

Anogenital warts are papillomatous growths that occur throughout the anogenital skin and mucosa, typically at sites of genital friction. HPV types 6 or 11 are found in about 85% of cases, with approximately half of infected persons developing warts. Perianal warts (Chapter 131) are most common in persons with a history of anal intercourse and are often associated with intra-anal warts, but they also can occur without such contact, such as through autoinoculation when wiping. Anogenital warts can range from flat or papular lesions to the classic pedunculated, cauliflower-shaped condyloma acuminatum. Warts are typically asymptomatic, noticed either by the patient as a "bump" or inadvertently during a genital examination, although they can cause itching, burning, pain, or, rarely, bleeding. In pregnant women mechanical obstruction of the birth canal has been reported.

The most common clinical manifestations of oral HPV infection include oral squamous cell papillomas and condyloma acuminatum, which are caused by HPV types 6 and 11. Oropharyngeal precancers and cancers can present with painful ulcers, dysphagia, bleeding, and/or lymphadenopathy. Less frequent, and differentiated by histology, are common skin warts caused by cutaneous HPV. Focal epithelial hyperplasia is an uncommon disorder with a predilection for Native Americans and South Africans. It presents as round, flat papules that can be confluent and are mostly associated to HPV types 13 and 32. Warts caused by genital types can also rarely occur in the upper respiratory tract, where they produce a serious recurrent respiratory papillomatosis that can cause hoarseness and even compromise the airway.

Squamous intraepithelial lesions or intraepithelial neoplasias are most commonly found on the cervix as a result of screening for cervical cancer by cytology (Papanicolaou [Pap] test) or HPV molecular testing, with confirmation by colposcopy and biopsy. In late stages, cervical cancer can present with abnormal vaginal bleeding, pelvic pain, and dyspareunia. Potential precursors of cancer and resulting cancers also can occur at other anogenital sites (vulva, vagina, anus,[10] and penis[11]). Most squamous intraepithelial lesions are not visible on mucosal surfaces without the application of 3 to 5% acetic acid and magnification. On the external genitalia, they can appear as flat hyperpigmented papules.

FIGURE 344-1. Plantar wart. A hyperkeratotic, verrucous papule or plaque beneath a pressure point on the sole of the foot is characteristic. HPV types 1 (myrmecia), 2 (mosaic), and 4 are most common. Because plantar warts are driven into the skin by the pressure of walking or standing, they are usually the most treatment resistant.

DIAGNOSIS

Both cutaneous (Fig. 344-1) and genital (Fig. 344-2) warts generally present an easily recognized clinical picture and can be diagnosed by history and physical examination without laboratory testing. Oral lesions are also generally recognized by history and physical examination.

The differential diagnosis of cutaneous warts includes seborrheic and solar keratoses, nevi, irritated acrochordons, corns (also called calluses or clavi), and squamous cell carcinoma (Chapters 188 and 407), whereas plantar warts can be mimicked by lichen planus (Chapter 405) and corns of the foot. The differential diagnosis of genital warts includes benign papular lesions (e.g., seborrheic keratoses, acrochordons, and pearly penile papules) or inflammatory conditions (e.g., lichen planus, lichen nitidis). Genital warts must be distinguished from other sexually transmitted infections: the condylomata lata lesions of secondary syphilis (Chapter 295), which are typically flat-topped, moist, and kissing lesions, and molluscum contagiosum, which presents as smooth, dome-shaped papules, typically with a central dimple (Chapter 407). Biopsy for histopathologic examination may be helpful for lesions at all anatomic sites that are atypical or not responsive to therapy, those suggestive of high-grade squamous intraepithelial lesions or cancer (e.g., pigmented, indurated, fixed, bleeding, or ulcerated), or lesions in immunocompromised patients. HPV testing is not recommended for diagnosis because it cannot confirm the diagnosis and is not useful in guiding management.

Cervical squamous intraepithelial lesions have traditionally been detected by cervical cytology through Pap tests, with assessment of abnormal results by colposcopy and biopsy for histopathologic examination. However, HPV testing is more sensitive than Pap tests for detecting cervical intraepithelial neoplasia 2/3,[A1] and, used either alone or in combination with cytology (co-testing) in women over age 30 years, can permit the interval between screening to increase from every 3 years to every 5 years.[12] HPV tests are also recommended

for triage of women whose Pap test results show atypical squamous cells of undetermined significance, which is an equivocal test result. HPV testing has not been validated and is not recommended for screening for infection at other sites (e.g., anus, oropharynx), although it can assist with staging and prognosis of oropharyngeal cancer.

TREATMENT

Management of HPV infection is directed toward diagnosis and treatment of the lesions themselves because there are no virus-specific therapies. Many lesions resolve spontaneously, so the goal of treatment is amelioration or prevention of symptoms or, in the case of high-grade squamous intraepithelial lesions, prevention of progression to cancer. Treatment involves destruction of lesions by physical techniques or topically applied or injected cytotoxic agents. Because treatment does not eradicate infection in surrounding tissues, recurrent lesions are common.

Treatment of warts depends on their location and size, patient's preferences, and the clinician's experience. Recommended first-line treatment of common and plantar warts is the application of topical salicylic acid; second-line treatment of recalcitrant lesions includes cryotherapy (which also can be used for flat warts),[A2] intralesional bleomycin, pulsed dye laser therapy, and surgical excision. Recommended treatments of genital warts (Table 344-1) include patient-applied podophyllotoxin (0.5% solution or gel applied twice a day for 3 days, repeated weekly for four cycles), imiquimod, or sinecatechins, as well as provider-administered cryotherapy, trichloroacetic acid, or surgical excision; alternative treatments include laser surgery, infrared coagulation, and electrosurgery.[A3] Oral lesions can be treated by locally destructive physical techniques (cold-blade excision, cryotherapy, or laser surgery), whereas options for laryngeal papillomas include microdébridement, laser surgery, or photodynamic laser therapy.

For cervical lesions, treatment depends on histologic staging after colposcopy and biopsy and clinical context.[13] The general principles are as follows. Because cervical intraepithelial neoplasia grade 1 usually regresses spontaneously, follow-up (by cytology, HPV test, or colposcopy) without treatment is recommended. For cervical intraepithelial neoplasia grade 2/3 lesions, treatment is generally recommended, except in pregnant women, who have higher rates of spontaneous regression and a greater risk of reproductive tract complications after treatment, and in young women with cervical intraepithelial neoplasia grade 2. Treatment options include a variety of ablative and excisional techniques such as cryosurgery, loop electrosurgical excision procedure, and laser surgery. Treatment is 90 to 95% effective in preventing the recurrence of lesions, and comparative clinical trials have shown similar efficacy for different treatment modalities.

PREVENTION

Primary Prevention

Primary prevention of HPV infection depends on avoidance of contact with infectious lesions and reduction of susceptibility through immunization. For example, the use of footwear in locker rooms may prevent plantar warts. For genital HPV infection, correct and consistent condom use can reduce the risk for both HPV infection and the HPV-associated diseases of genital warts, cervical squamous intraepithelial lesions, and cervical cancer. Condom use also assists in the clearance of existing cervical HPV lesions. Male circumcision may reduce the prevalence of genital HPV infection in men, but whether it affects the transmission or clearance of these infections is unclear.[A4]

TABLE 344-1 RECOMMENDED TREATMENT OF GENITAL WARTS

PATIENT APPLIED
Podophyllotoxin (podofilox) 0.5% solution or gel; to be applied in up to 4 weekly cycles (twice daily for 3 days, followed by 4 days without treatment)
Imiquimod 3.75% cream (to be applied once daily at bedtime) or 5% cream (to be applied once at bedtime 3 times per week) for 6-10 hours for up to 16 weeks
Sinecatechins 15% ointment; to be applied 3 times daily for up to 16 weeks
PROVIDER ADMINISTERED
Cryotherapy with liquid nitrogen or cryoprobe; to be applied once every 1-2 weeks*
Trichloroacetic or bichloroacetic acid 80-90% solution; to be applied once weekly*
Office surgery* (excision, electrocautery, curettage)

*Safe for use in pregnancy.

Modified from: Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64:1-137.

TABLE 344-2 U.S. ADVISORY COMMITTEE ON IMMUNIZATION PRACTICES RECOMMENDATIONS FOR HPV VACCINATION*

WHOM TO VACCINATE
Immunocompetent population • At age 11-12 years (but may start as early as age 9; it should start at age 9 in children with a history of sexual abuse or assault) • Catch-up HPV vaccination is recommended for all persons through age 26 years who are not adequately vaccinated • Shared clinical decision-making regarding HPV vaccination is recommended for adults ages 27 through 45 years who are not adequately vaccinated
Immunocompromised persons • 3 doses of HPV vaccine (0, 1-2, 6 months) are recommended for persons ages 9 through 26 years with immunocompromising conditions that might reduce cell-mediated or humoral immunity (e.g., B lymphocyte antibody deficiencies, T lymphocyte defects, HIV, malignancy, transplantation, autoimmune disease, or immunosuppressive therapy); the 3 dose recommendation does not apply to children ages <15 years with asplenia, asthma, chronic granulomatous disease, chronic liver disease, chronic lung disease, chronic renal disease, central nervous system anatomic barrier defects (e.g., cochlear implant), complement deficiency, diabetes, heart disease, or sickle cell disease
HOW TO VACCINATE
Recommended dosage and schedule: 0.5 mL intramuscularly • If vaccination is initiated before age 15 years, give 2-dose schedule: 0 and 6-12 months • If vaccination is initiated at age 15 years or older, give 3-dose schedule: 0, 1-2 months, and 6 months
SPECIAL CONSIDERATIONS
Schedule modifications: If the vaccination schedule is interrupted, the series does not need to be restarted but should be completed as soon as possible
Cervical cancer screening: no change in recommended interval
Special situations: females with genital warts, abnormal Pap test results, or positive HPV test results are unlikely to be infected with all vaccine types and should be immunized per other recommendations; males with genital warts should also be immunized per other recommendations
Pregnant and lactating women: not recommended for use in pregnancy based on lack of data; may be used in lactating women
Not recommended for females or males <9 and >45 years of age

*These recommendations have been adapted to reflect that (Gardasil-9) is the only available HPV vaccine in the United States.

Modified from:

Meites E, Kempe A, Markowitz LE. Use of a 2-dose schedule for human papillomavirus vaccination—updated recommendations of the Advisory Committee on Immunization Practices. *MMWR Morb Mortal Wkly Rep.* 2016;65:1405-1408.

Meites E, Szilagyi PG, Chesson HW, Unger ER, Romero JR, Markowitz LE. Human papillomavirus vaccination for adults: updated recommendations of the Advisory Committee on Immunization Practices. *MMWR Morb Mortal Wkly Rep.* 2019 Aug 16;68(32):698-702.

Of greatest importance for prevention are HPV vaccines (Chapter 15), which are composed of virus-like particles assembled from the major capsid protein, L1 (Table 344-2). Gardasil-9 is a nonavalent vaccine that includes types 6, 11, 16, and 18, 31, 33, 45, 52, 58. In addition to protecting against cervical intraepithelial neoplasia, cervical adenocarcinoma in situ, and cancer, it also protects against vulvar intraepithelial neoplasia, vaginal intraepithelial neoplasia, and cancers of the vulva or vagina in females, as well as against anal intraepithelial neoplasia[A5,A6] and anal cancer in males. In addition, vaccination protects both males and females against genital warts,[A7] and it reduces persistent oral HPV infections.[14] Cervarix, which is a bivalent (types 16 and 18) vaccine, is approved for the prevention of cervical intraepithelial neoplasia, cervical adenocarcinoma in situ, and cancer of the cervix associated with these two HPV types. Gardasil-9 is now the only vaccine available in the United States. HPV vaccination has no therapeutic benefit against existing infections or lesions but may lower the rate of disease recurrence after successful treatment. It is important to administer the vaccine before the onset of sexual activity to have the fullest benefit.

Other than transient local side effects at the site of intramuscular injection, mostly related to the adjuvant, the HPV vaccines have been very safe.[15] The longevity of protection is not yet established but has reached at least 14 years with the 3-dose regimen.[16] Two-dose regimens appear to be as good as 3-dose regimens,[17] with both regimens providing excellent and durable

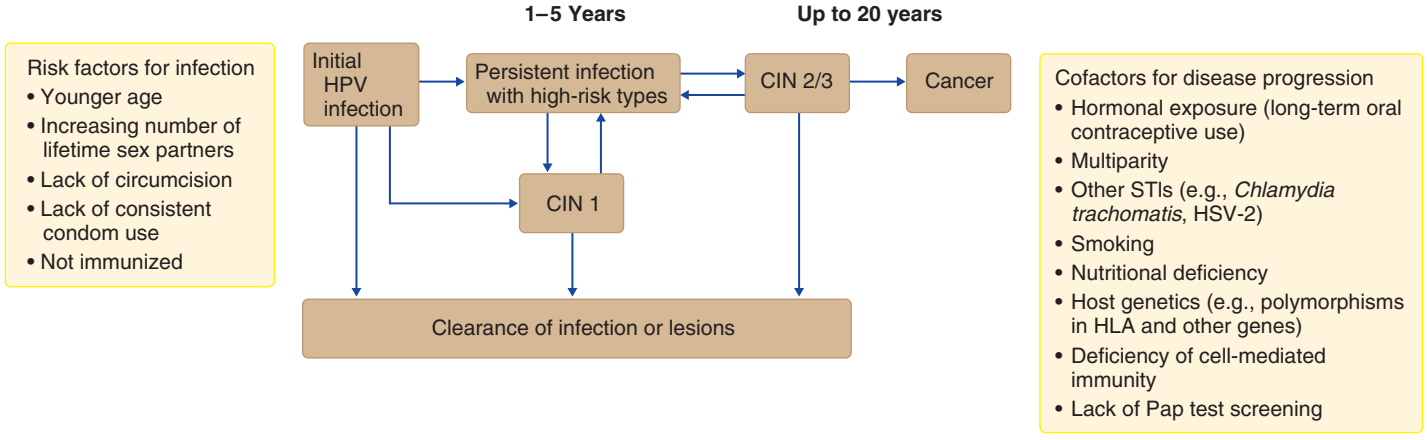

FIGURE 344-3. Natural history of genital human papillomavirus (HPV) infection and cervical cancer. CIN = cervical intraepithelial neoplasia; HSV = herpes simplex virus; STIs = sexually transmitted infections.

antibody response.[A8,A9] The HPV vaccine does not contain any live virus and can be given safely to immunocompromised persons.

Secondary Prevention

Screening plus treatment of high-grade cervical squamous intraepithelial lesions is one of the most successful of all cancer prevention strategies (see Chapter 184). HPV vaccination status currently does not alter recommendations regarding screening for cervical cancer. This recommendation could change in the future, however, if high vaccine coverage continues to lower the prevalence rates of cervical HPV infections. The value of cytologic screening for anal intraepithelial lesions (Chapter 131) in HIV-positive men who have sex with men is controversial but not currently recommended because of limited data on the natural history of these precursor lesions, the reliability of screening methods, and the safety and effectiveness of treatment.

PROGNOSIS

The large majority of HPV infections and related premalignant lesions resolve spontaneously in most immunocompetent patients based on their cell-mediated immunity. Spontaneous regression within a year is estimated to occur in 25% of genital warts and more than 50% of common warts in children. Whether infections no longer detectable have been cleared by the immune system or remain latent in the basal layer of the epithelium with the potential for reactivation is not clear, but the higher prevalence of detectable infection in advanced than in early HIV infection, as well as in immunosuppressed individuals, supports the possibility of long-term infection.

For cervical intraepithelial neoplasia, rates of regression are higher at younger ages and with lower grade lesions. The majority of grade 1 and 2 cervical intraepithelial neoplasia lesions regress spontaneously, whereas over 30% of women with grade 3 will progress to invasive cancer without treatment. The grades of cervical intraepithelial neoplasia may represent either a continuum of the same process or distinct processes, in which grade 1 cervical intraepithelial neoplasia represents a usually transient infection characterized by production of capsid protein (and probably infectious virions) and only minor cellular abnormalities, whereas grades 2 and 3 represent proliferation of immature cells as a result of the activity of oncogenic proteins of high-risk types (Fig. 344-3). Initial infection frequently leads to a transient low-grade squamous intraepithelial lesion, with persistent infection in less than 10% of cases. Persistent infection can, however, lead directly to high-grade squamous intraepithelial lesions within several years and can progress to invasive cancer after several decades, with the likelihood of cancer enhanced by cofactors such as older age and immunosuppression.[18] The natural history of squamous intraepithelial lesions at other anogenital sites is less well defined, but they may have higher rates of spontaneous regression.

The majority of patients with HPV infection have an excellent prognosis, with cancer occurring infrequently among the large number of persons infected. Treatment can hasten the resolution of cutaneous and genital warts and is highly effective for cervical lesions. Among women with cervical intraepithelial neoplasia grade 3, long-term studies indicate that the 30% risk of cancer in untreated women can be reduced to less than 1% with treatment.

345 HERPES SIMPLEX VIRUS INFECTIONS

RICHARD J. WHITLEY AND JOHN W. GNANN, JR.

DEFINITION

The Pathogen

Among the herpesviruses, HSV-1 and HSV-2 are most closely related, with approximately 60% genomic homology. Historically, HSV-1 was more frequently associated with nongenital (especially orolabial) disease and HSV-2 with genital disease, but that distinction has become blurred with the recognition that HSV-1 causes more than half of initial genital herpes infections in some populations. These two viruses can be distinguished most reliably by DNA analysis, but differences in antigen expression and biologic properties also serve as methods for differentiation.

antibody response.[A8,A9] The HPV vaccine does not contain any live virus and can be given safely to immunocompromised persons.

Secondary Prevention

Screening plus treatment of high-grade cervical squamous intraepithelial lesions is one of the most successful of all cancer prevention strategies (see Chapter 184). HPV vaccination status currently does not alter recommendations regarding screening for cervical cancer. This recommendation could change in the future, however, if high vaccine coverage continues to lower the prevalence rates of cervical HPV infections. The value of cytologic screening for anal intraepithelial lesions (Chapter 131) in HIV-positive men who have sex with men is controversial but not currently recommended because of limited data on the natural history of these precursor lesions, the reliability of screening methods, and the safety and effectiveness of treatment.

PROGNOSIS

The large majority of HPV infections and related premalignant lesions resolve spontaneously in most immunocompetent patients based on their cell-mediated immunity. Spontaneous regression within a year is estimated to occur in 25% of genital warts and more than 50% of common warts in children. Whether infections no longer detectable have been cleared by the immune system or remain latent in the basal layer of the epithelium with the potential for reactivation is not clear, but the higher prevalence of detectable infection in advanced than in early HIV infection, as well as in immunosuppressed individuals, supports the possibility of long-term infection.

For cervical intraepithelial neoplasia, rates of regression are higher at younger ages and with lower grade lesions. The majority of grade 1 and 2 cervical intraepithelial neoplasia lesions regress spontaneously, whereas over 30% of women with grade 3 will progress to invasive cancer without treatment. The grades of cervical intraepithelial neoplasia may represent either a continuum of the same process or distinct processes, in which grade 1 cervical intraepithelial neoplasia represents a usually transient infection characterized by production of capsid protein (and probably infectious virions) and only minor cellular abnormalities, whereas grades 2 and 3 represent proliferation of immature cells as a result of the activity of oncogenic proteins of high-risk types (Fig. 344-3). Initial infection frequently leads to a transient low-grade squamous intraepithelial lesion, with persistent infection in less than 10% of cases. Persistent infection can, however, lead directly to high-grade squamous intraepithelial lesions within several years and can progress to invasive cancer after several decades, with the likelihood of cancer enhanced by cofactors such as older age and immunosuppression.[18] The natural history of squamous intraepithelial lesions at other anogenital sites is less well defined, but they may have higher rates of spontaneous regression.

The majority of patients with HPV infection have an excellent prognosis, with cancer occurring infrequently among the large number of persons infected. Treatment can hasten the resolution of cutaneous and genital warts and is highly effective for cervical lesions. Among women with cervical intraepithelial neoplasia grade 3, long-term studies indicate that the 30% risk of cancer in untreated women can be reduced to less than 1% with treatment.

345 HERPES SIMPLEX VIRUS INFECTIONS

RICHARD J. WHITLEY AND JOHN W. GNANN, JR.

DEFINITION

The Pathogen

Among the herpesviruses, HSV-1 and HSV-2 are most closely related, with approximately 60% genomic homology. Historically, HSV-1 was more frequently associated with nongenital (especially orolabial) disease and HSV-2 with genital disease, but that distinction has become blurred with the recognition that HSV-1 causes more than half of initial genital herpes infections in some populations. These two viruses can be distinguished most reliably by DNA analysis, but differences in antigen expression and biologic properties also serve as methods for differentiation.

ABSTRACT

Herpes simplex virus (HSV) is one of the most common causes of human infections. The virus, which is an *alpha herpesvirus,* has the unique biologic characteristic of establishing latency in sensory ganglia and then periodically reactivating with the proper provocative stimulus and causing recurrent disease. Infection is transmitted from person-to-person via direct contact. Transmission most often occurs in the absence of clinical symptoms. There are two distinct antigenic types of HSV: HSV-1 and HSV-2. HSV-1 is usually associated with infections involving the oropharynx and lips, but the number of genital infections attributed to HSV-1 in the United States has increased significantly. HSV-2 routinely causes infections involving the genitalia and adjacent areas (pubis, buttocks, thighs, etc.). HSV disease can range from benign to life-threatening. The most severe manifestations are neonatal HSV infection (HSV-1 or HSV-2) and HSV encephalitis (usually HSV-1). Diagnosis is achieved either by polymerase chain reaction assays or by culture. Antiviral therapy is available to ameliorate the severity of the disease.

KEYWORDS

herpes simplex virus
infection
Herpesviridae

antivirals
encephalitis
neonatal herpes simplex virus

Inclusion in the family Herpesviridae is based on the structure of the virion (E-Fig. 345-1). HSV contains double-stranded DNA at its central core, has a molecular weight of approximately 100 million, and its 152- kb genome encodes at least 80 polypeptides. The DNA core is surrounded by a capsid that consists of 162 capsomers arranged in icosahedral symmetry. The capsid is 100 to 110 nm in diameter. Tightly adherent to the capsid is the tegument, which consists of amorphous material. Loosely surrounding the capsid and tegument is a lipid bilayer envelope derived from host cell membranes. The envelope consists of polyamines, lipids, and glycoproteins. These glycoproteins confer distinctive properties to the virus and are antigenic targets for host immune responses. Notably, glycoprotein G (gG) provides antigenic specificity to HSV, thereby resulting in an antibody response that allows serologic distinction between HSV-1 (gG-1) and HSV-2 (gG-2).

EPIDEMIOLOGY

HSV infections are very common worldwide in both developed and developing countries, without any seasonal variations. HSV is transmitted from infected to susceptible individuals during close personal contact; the virus must come in contact with a mucosal surface or abraded skin for infection to be initiated. Because over half of the world's population has HSV infections and because such infections are rarely fatal, a large reservoir of HSV exists to perpetuate person-to-person transmission. No animal vectors have been identified.

Seroprevalence studies have demonstrated that acquisition of HSV-1 infection is related to socioeconomic and behavioral factors. Antibodies, which indicate past infection, are found early in life among individuals of lower socioeconomic groups, presumably as a consequence of crowded living conditions that provide a greater opportunity for direct contact with infected individuals. Antibodies develop in as many as 75 to 90% of individuals from lower socioeconomic populations by the end of the first decade of life. In contrast, only 30 to 40% of persons in the middle and upper socioeconomic groups are seropositive by the middle of the second decade of life.

Because infections with HSV-2 are usually acquired through sexual contact, antibodies to this virus are rarely found before the onset of sexual activity, but the incidence of HSV-2 progressively increases in all populations beginning in adolescence.[1] Overall, about 15 to 20% of Americans have genital HSV-2 infection. Rates of HSV-2 infection are highest among women, non-Hispanic Blacks, men who have sex with men, and immunocompromised persons, including persons positive for human immunodeficiency virus (HIV; Chapter 358). Genital herpes infection is an important risk factor for HIV transmission. (Chapter 355). The lifetime costs of genital herpes infection are estimated to be about $1000 per treated case.[2]

Genital HSV disease occurring during gestation can result in transmission of HSV to the fetus, most frequently resulting from shedding of the virus in genital secretions at the time of delivery. Women who experience a symptomatic or asymptomatic primary infection in the third trimester of gestation have a 30 to 50% risk for transmitting infection to the child. The incidence of cervical shedding in pregnant women with asymptomatic chronic HSV-2 infection is approximately 1%. Most infants who develop neonatal disease are born to women who are completely asymptomatic for genital HSV infection at the time of delivery and who have neither a known history of genital herpes nor a sexual partner who has reported a genital rash.

PATHOBIOLOGY

Replication of HSV is a multistep process (E-Fig. 345-2). After binding of the virion to the host cell and release of the nucleocapsid into the cytoplasm, DNA is uncoated and transported to the nucleus. This release is followed by transcription of immediate-early genes, which encode the regulatory proteins, and is followed sequentially by the expression of proteins encoded by early and late genes. These proteins include structural proteins and enzymes necessary for viral replication.

Assembly of the viral core and capsid takes place within the nucleus. Envelopment at the nuclear membrane and transport out of the nucleus occur through the endoplasmic reticulum and the Golgi apparatus. Glycosylation of the viral membrane occurs in the Golgi apparatus. Mature virions are transported to the outer membrane of the host cell inside vesicles. Release of progeny virus is accompanied by cell death.

A critical factor for transmission of HSV is intimate contact between a person who is shedding virus and a susceptible host. Following inoculation onto skin or mucous membranes, HSV replicates in epithelial cells; the incubation period is 4 to 6 days (E-Fig. 345-3). Importantly, most primary infections are asymptomatic. In symptomatic patients, cell lysis and local inflammation ensue as replication continues, thereby resulting in the formation of characteristic vesicles on erythematous bases. During primary infection, lymph nodes in the area of viral replication may become enlarged. Viremia may result in visceral dissemination in immunocompromised patients. In all hosts, the virus generally ascends peripheral sensory nerves to reach the dorsal root ganglia. Replication of HSV within neural tissue is followed by spread of the virus to other mucosal and skin surfaces by means of peripheral sensory nerves. HSV replicates further in epithelial cells and reproduces the lesions of the initial infection until infection is contained through host immune responses.

The histopathologic changes induced by HSV replication are similar in both primary and recurrent infection, including ballooning of infected cells and the appearance of condensed chromatin within the nuclei of cells, followed by degeneration of cellular nuclei. Cells lose intact plasma membranes and form multinucleated giant cells. They may also demonstrate intranuclear inclusions, which are known as Cowdry type A bodies, and which are suggestive, but not diagnostic, of HSV infection. With cell lysis, clear vesicular fluid containing large quantities of virus accumulates between the epidermis and dermal layer. The dermis reveals an intense inflammatory response, more so with primary infection than with recurrent disease. As healing progresses, the clear vesicular fluid becomes pustular with the accumulation of inflammatory cells. The pustule ruptures, thereby resulting in an ulcer, which then scabs and heals; scarring is uncommon.

Vascular changes in the area of infection include perivascular cuffing and hemorrhagic necrosis. These changes are particularly prominent when organs other than skin are involved, as is the case with herpes simplex encephalitis or disseminated neonatal HSV infection. As host defenses are mounted, an influx of mononuclear cells is seen in infected tissue.

A unique characteristic of all herpesviruses is their ability to establish latent infection by persisting in an apparently inactive state for varying lengths of time and then reactivating (E-Fig. 345-4).[3] The latent viral genome may be either extrachromosomal or integrated into host cell DNA, depending on the type of herpesvirus.

Latency is established when HSV reaches the dorsal root ganglia after retrograde transmission through sensory nerve pathways. Latent virus may be reactivated and enter a replicative cycle at any point in time. Reactivation of latent virus is a well-recognized clinical phenomenon, but the molecular mechanisms remain incompletely understood. Stimuli associated with the reactivation of latent HSV include stress, fever, menstruation, and exposure to ultraviolet light. Precisely how these factors interact with latent virus at the level of the ganglia remains undefined. Reactivation is often clinically asymptomatic, but it may occasionally produce life-threatening disease.

HSV has been used for experimental gene therapy. By removal of the $\gamma_1$34.5 gene, both neurovirulence and the propensity to establish latency are ablated. These engineered viruses are being experimentally tested in patients with glioblastoma multiforme (Chapter 175) and metastatic colorectal cancer (Chapter 179).

CLINICAL MANIFESTATIONS

Gingivostomatitis

Gingivostomatitis (usually caused by HSV-1) occurs most frequently in children younger than 5 years. Illness is characterized by fever, sore throat, pharyngeal edema, and erythema, followed by the development of vesicular or ulcerative lesions on the oral and pharyngeal mucosa. Recurrent HSV-1 infections of the oropharynx, which have a significant adverse effect on quality of life,[4] are most frequently manifested as herpes simplex labialis (cold sores or fever blisters) and usually appear at the vermilion border of the lip (Fig. 345-1). Recurrences are triggered by fever, stress, physical injury, immunosuppression, menstruation, and exposure to ultraviolet light. Intraoral ulcers as a manifestation of recurrent HSV disease are uncommon.

Genital Herpes

Only 10 to 25% of persons with serologically confirmed HSV-2 infection are aware that they have genital herpes. Investigations using serial polymerase chain reaction (PCR) sampling have shown that 80 to 90% of HSV-2–infected individuals have transient episodes of asymptomatic viral shedding from the genital tract on 10 to 20% of days. Asymptomatic viral shedding from undiagnosed patients is the most common source of new transmissions.

Symptomatic initial infection in women usually involves lesions on the vulva, vagina, and cervix, whereas symptomatic men experience lesions on the glans penis, prepuce, or penile shaft. In the United States, herpes simplex

FIGURE 345-1. Herpes labialis, classic grouped blisters.

is the most common cause of genital ulcers (Chapter 264).[5] Although genital herpes was historically attributed to HSV-2, over 50% of all initial cases in some populations (especially young women, non-Hispanic Whites, and men who have sex with men) are caused by HSV-1.

In individuals of either gender, primary disease can be associated with fever, malaise, anorexia, and bilateral inguinal adenopathy. Following initial infection, complete healing of lesions may take 2 to 3 weeks. Women frequently have dysuria and urinary retention as a result of urethral involvement. Aseptic meningitis (Chapter 381) develops in as many as 10% of individuals with primary infection. Sacral radiculomyelitis, which may occur in both men and women, results in neuralgias, urinary retention, or obstipation.

The initial episode of genital infection is less severe in individuals who have previously had HSV-1 infections at other sites. Antibodies to HSV-1 appear to ameliorate the clinical severity of initial HSV-2 infection.

Recurrent genital infections in either men or women can be particularly distressing. The frequency of recurrences varies significantly from one individual to another, but is always less frequent with HSV-1 genital disease than with HSV-2. In the first year after initial genital herpes caused by HSV-2, the median number of symptomatic recurrences is four.

Herpetic Keratitis

Herpes simplex keratitis (see Fig. 391-17), which is usually caused by HSV-1 and is often accompanied by conjunctivitis, is considered the most common infectious cause of blindness in the United States. The characteristic lesions of HSV keratoconjunctivitis are dendritic ulcers best detected by fluorescein staining of the cornea.[6] Deep stromal involvement also may result in visual impairment.

Other Cutaneous Manifestations

HSV infections can occur at any skin site. Common among health care workers are lesions on the fingers, known as herpetic whitlow. Similarly, wrestlers can develop cutaneous lesions known as herpes gladiatorum as a result of physical contact.

Herpes Meningitis

Reactivation of HSV-2 that is associated with symptomatic or asymptomatic genital herpes can cause recurrent episodes of lymphocytic meningitis (Chapter 381).[7] Symptoms include fever, meningismus, and headache, which can be severe. HSV meningitis is usually self-limited and does not progress to herpes encephalitis.

Hepatic Disease

An uncommon but potentially lethal syndrome of acute hepatic necrosis[8] caused by HSV has been described in both immunocompetent and immunocompromised patients. It occurs with increased frequency in pregnant women.

HERPES SIMPLEX VIRUS INFECTIONS IN IMMUNOCOMPROMISED HOSTS

HSV infections in immunocompromised hosts, including patients with acquired immunodeficiency syndrome, are usually due to reactivation of latent infection and are clinically more severe, may be progressive, and require a longer time to heal. Manifestations of HSV infections in this population include pneumonitis,[9] esophagitis, hepatitis, colitis, disseminated cutaneous disease, and central nervous system (CNS) infections. Individuals suffering from HIV infection may have extensive perineal or orofacial ulcerations. HSV infections can also be severe in individuals with extensive burns.

DIAGNOSIS

Definitive diagnosis of HSV infection requires detection of viral DNA by PCR testing or isolation of virus. DNA amplification has become the diagnostic method of choice in assessing cerebrospinal fluid (CSF) specimens for evidence of HSV infection of the central nervous system.[10] PCR is now widely used for confirmation of HSV as the cause of mucocutaneous or ocular infections. Viral culture is no longer frequently used, but is essential when an HSV isolate is required to assess possible resistance to antiviral drugs.

In the absence of PCR or diagnostic virologic facilities, cytologic examination of cells scraped from a clinical lesion may be useful in making a presumptive diagnosis of HSV infection (Tzanck prep), although sensitivity is low. Staining the preparation with HSV-specific monoclonal antibodies improves the sensitivity of the technique.

Type-specific serologic assays that reliably establish whether an individual is infected with HSV-1 or HSV-2 (or both) are commercially available. These tests are based on antigenic differences between HSV-1 and HSV-2 glycoprotein G.

TREATMENT

Immunocompromised Patients

For immunocompromised patients with extensive cutaneous HSV disease or with visceral organ disease, the treatment of choice is intravenous acyclovir (5 to 10 mg/kg every 8 hours, with dose adjustment for renal function). Acyclovir therapy is associated with very few adverse events. However, caution must be exercised when acyclovir is administered intravenously because the drug may crystallize in the renal tubules when infused too rapidly, especially in patients who are volume depleted or have preexisting renal dysfunction. Valacyclovir (500 to 1000 mg two or three times daily) and famciclovir (250 to 500 mg two or three times daily) are orally administered antiviral drugs that have improved pharmacokinetic profiles compared with oral acyclovir. These drugs are effective alternatives for non–life-threatening HSV infections.

Immunocompromised patients are at risk for developing infection due to acyclovir-resistant HSV. Resistance is usually due to a mutation resulting in altered or deficient expression of thymidine kinase, an enzyme essential for activation of acyclovir. Such patients can be managed with intravenous foscarnet or cidofovir, although each of these drugs can cause significant adverse effects (see Tables 328-4 and 328-5 in Chapter 328).

Immunocompetent Patients

In immunocompetent hosts with recurrent genital or bothersome labial infections,[11] oral acyclovir (800 mg twice daily for 5 days) accelerates healing of the lesion.[A1] Oral valacyclovir (1g once daily for 5 days or 500 mg twice daily for 3 days) and oral famciclovir (1 g once daily for 1 day) are equally effective[A2] and more convenient. Topical acyclovir is minimally efficacious and is not recommended,[A3] although the combination of topical therapy and photodynamic therapy (local application of methylene blue as a photosensitizer followed by laser light at a 660- nm wavelength) may reduce pain.[A4] Herpes simplex keratitis usually resolves with ganciclovir 0.15% ophthalmic gel five times daily for at least 1 week or oral acyclovir 800 mg five times daily for 7-10 days, but it can recur (Chapter 391).

Immunocompetent patients with HSV meningitis typically improve with or without specific antiviral therapy. Their treatment can focus on rehydration and analgesia rather than intravenous acyclovir therapy.

PREVENTION

Secondary Prevention

All patients with symptomatic genital HSV recurrences should be considered candidates for long-term suppressive antiviral therapy. Recommended regimens include oral acyclovir 400 mg twice daily, oral valacyclovir 500 mg or 1 g once daily, and oral famciclovir 250 mg twice daily. Suppressive therapy, which is highly effective for preventing both symptomatic recurrences and asymptomatic viral shedding, is much more efficient for genital herpes than is episodic antiviral therapy of symptomatic recurrences.

Suppressive therapy is not recommended for herpes labialis, for which the benefit of viral suppression is small. Antiviral suppressive therapy does not reliably prevent recurrent HSV-2 meningitis. Acyclovir, valacyclovir, and famciclovir are given to recipients of solid organ and bone marrow transplants in the immediate post-transplantation period to prevent reactivation of latent infection (see Tables 328-4 and 328-5).

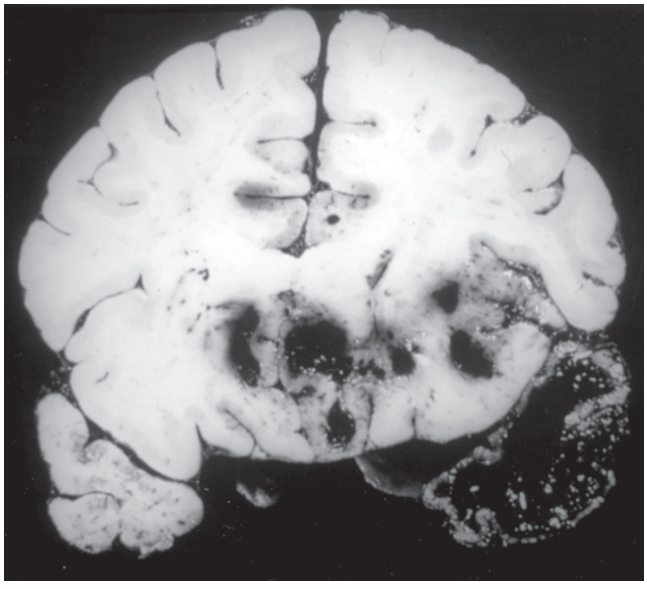

FIGURE 345-2. Hemorrhagic temporal lobe necrosis in herpes simplex encephalitis.

Primary Prevention

Screening of asymptomatic patients for genital HSV infection is not recommended. Vaccines for HSV-1 and HSV-2 remain investigational.[12] In a randomized trial, pericoital use of tenofovir gel, an antiviral microbicide, reduced HSV-2 acquisition in women by about 50%.[A5] Use of condoms also decreases transmission. Valacyclovir (500 mg daily) can decrease person-to-person transmission of HSV-2 when taken by the infected partner in a discordant couple. Suppressive therapy of an HSV-2–infected but HIV-seronegative person does not prevent HIV acquisition from HIV-seropositive partners.

HERPES SIMPLEX ENCEPHALITIS

Herpes simplex encephalitis is characterized by hemorrhagic necrosis of the temporal lobe (Chapter 383). Disease begins unilaterally and can spread to the contralateral temporal lobe (Fig. 345-2). It is the most common cause of fatal, sporadic encephalitis (Chapter 383) in the United States and occurs in approximately 1 to 2 cases per 500,000 individuals per year. More than 90% of cases in adults are caused by HSV-1. Herpes simplex encephalitis, which may follow primary or reactivated infection, can reach the temporal lobe by ascending neural pathways, such as the trigeminal tracts or the olfactory nerves. Defects in genes in the toll-like receptor 3 pathway increase risk for HSV encephalitis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical manifestations of herpes simplex encephalitis reflect temporal lobe involvement and include headache, fever, altered consciousness, behavioral changes, aphasia, and other focal neurologic abnormalities. Seizures are also common. CSF findings in these patients are variable, but usually reveal a lymphocytic pleocytosis (25 to 75 WBC/μL, 75 to 90% mononuclear cells). The protein concentration is mildly elevated (65 to 85 mg/dL), and the glucose level is usually normal. Magnetic resonance imaging (which is more sensitive than computed tomography) can suggest the diagnosis by demonstrating abnormalities of the temporal lobe, which are unilateral in the early stages of the disease.[13] Diagnosis can be confirmed detection of HSV DNA by PCR in the CSF.

TREATMENT AND PROGNOSIS

Without effective antiviral therapy, mortality is over 70%, and less than 10% of patients return to baseline neurologic function. With appropriate therapy using intravenous acyclovir (10 mg/kg every 8 hours for 14 to 21 days), the mortality rate can be reduced to 10 to 25%, with 40 to 55% of patients able to resume their activities of daily living.[14] Long-term oral valacyclovir administration has no benefit following acyclovir treatment.[A6]

Instances of recurrent HSV encephalitis have been reported, but many cases of relapsing neurologic symptoms are now thought to be due to postinfectious autoimmune phenomena, especially anti-*N*-methyl-D-aspartate receptor antibody encephalitis (Chapter 383).[15]

NEONATAL HERPES SIMPLEX VIRUS INFECTION

Neonatal HSV infection is estimated to occur in approximately 1 in 2000 to 3500 deliveries in the United States each year. Approximately 70% of cases are caused by HSV-2 and usually result from contact of the fetus with infected maternal genital secretions at the time of delivery. Manifestations of neonatal HSV infection can be divided into three categories: skin, eye, and mouth disease; encephalitis; and disseminated infection. As the name implies, skin, eye, and mouth disease is characterized by cutaneous lesions and does not involve other organ systems. Involvement of the CNS may occur with encephalitis or disseminated infection and generally results in diffuse encephalitis. Disseminated infection involves multiple organ systems and can cause disseminated intravascular coagulation, hemorrhagic pneumonitis, encephalitis, and cutaneous lesions.

Diagnosis is difficult in the absence of skin lesions, which occurs in as many as 36% of cases. CSF analysis characteristically reveals elevated protein levels and mononuclear pleocytosis.

Antiviral therapy is intravenous acyclovir, 20 mg/kg every 8 hours for 14 days for skin, eye, and mouth infections and 21 days for central nervous system or disseminated disease.[16] Six months of suppressive acyclovir therapy (300 mg three times daily) can significantly improve neurologic outcome.

Even with appropriate antiviral treatment, the mortality rate for each disease classification varies from zero for skin, eye, and mouth disease to 5% for encephalitis and up to 25% for neonates with disseminated infection. In addition to this high mortality rate, children with encephalitis or disseminated disease develop normally in only 40% of cases.

346 VARICELLA-ZOSTER VIRUS (CHICKENPOX, SHINGLES)

JEFFREY COHEN

DEFINITION

Primary infection with varicella-zoster virus results in the rash of varicella (chickenpox). The varicella-zoster virus establishes a latent infection in the nervous system and can reactivate later in life to cause zoster (shingles).

The Pathogen

Varicella-zoster virus is a member of the alpha herpesvirus family and has a DNA core surrounded by a nucleocapsid, which is in turn surrounded by a viral envelope that is studded with glycoproteins. Antibody to viral glycoproteins is important for neutralizing the virus's infectivity and for protecting against primary infection. The virus encodes a thymidine kinase, which phosphorylates acyclovir, which in turn inhibits viral DNA replication by inhibiting the varicella-zoster virus DNA polymerase.

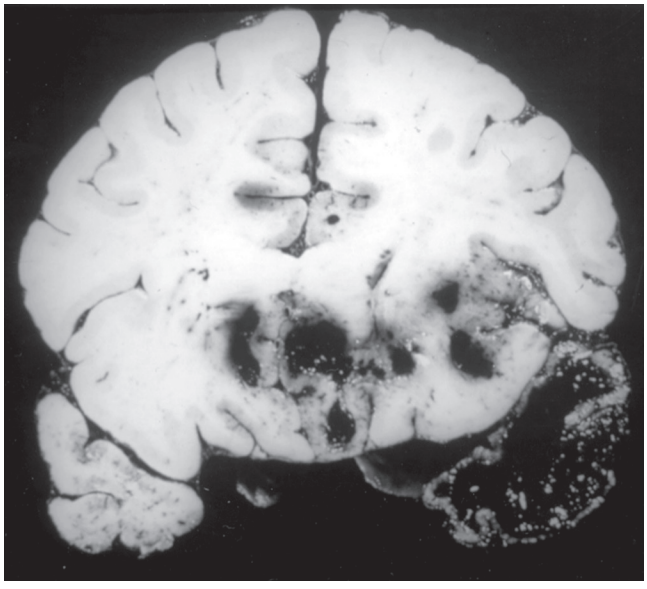

FIGURE 345-2. Hemorrhagic temporal lobe necrosis in herpes simplex encephalitis.

Primary Prevention

Screening of asymptomatic patients for genital HSV infection is not recommended. Vaccines for HSV-1 and HSV-2 remain investigational.[12] In a randomized trial, pericoital use of tenofovir gel, an antiviral microbicide, reduced HSV-2 acquisition in women by about 50%.[A5] Use of condoms also decreases transmission. Valacyclovir (500 mg daily) can decrease person-to-person transmission of HSV-2 when taken by the infected partner in a discordant couple. Suppressive therapy of an HSV-2–infected but HIV-seronegative person does not prevent HIV acquisition from HIV-seropositive partners.

HERPES SIMPLEX ENCEPHALITIS

Herpes simplex encephalitis is characterized by hemorrhagic necrosis of the temporal lobe (Chapter 383). Disease begins unilaterally and can spread to the contralateral temporal lobe (Fig. 345-2). It is the most common cause of fatal, sporadic encephalitis (Chapter 383) in the United States and occurs in approximately 1 to 2 cases per 500,000 individuals per year. More than 90% of cases in adults are caused by HSV-1. Herpes simplex encephalitis, which may follow primary or reactivated infection, can reach the temporal lobe by ascending neural pathways, such as the trigeminal tracts or the olfactory nerves. Defects in genes in the toll-like receptor 3 pathway increase risk for HSV encephalitis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical manifestations of herpes simplex encephalitis reflect temporal lobe involvement and include headache, fever, altered consciousness, behavioral changes, aphasia, and other focal neurologic abnormalities. Seizures are also common. CSF findings in these patients are variable, but usually reveal a lymphocytic pleocytosis (25 to 75 WBC/μL, 75 to 90% mononuclear cells). The protein concentration is mildly elevated (65 to 85 mg/dL), and the glucose level is usually normal. Magnetic resonance imaging (which is more sensitive than computed tomography) can suggest the diagnosis by demonstrating abnormalities of the temporal lobe, which are unilateral in the early stages of the disease.[13] Diagnosis can be confirmed detection of HSV DNA by PCR in the CSF.

TREATMENT AND PROGNOSIS

Without effective antiviral therapy, mortality is over 70%, and less than 10% of patients return to baseline neurologic function. With appropriate therapy using intravenous acyclovir (10 mg/kg every 8 hours for 14 to 21 days), the mortality rate can be reduced to 10 to 25%, with 40 to 55% of patients able to resume their activities of daily living.[14] Long-term oral valacyclovir administration has no benefit following acyclovir treatment.[A6]

Instances of recurrent HSV encephalitis have been reported, but many cases of relapsing neurologic symptoms are now thought to be due to postinfectious autoimmune phenomena, especially anti-*N*-methyl-D-aspartate receptor antibody encephalitis (Chapter 383).[15]

NEONATAL HERPES SIMPLEX VIRUS INFECTION

Neonatal HSV infection is estimated to occur in approximately 1 in 2000 to 3500 deliveries in the United States each year. Approximately 70% of cases are caused by HSV-2 and usually result from contact of the fetus with infected maternal genital secretions at the time of delivery. Manifestations of neonatal HSV infection can be divided into three categories: skin, eye, and mouth disease; encephalitis; and disseminated infection. As the name implies, skin, eye, and mouth disease is characterized by cutaneous lesions and does not involve other organ systems. Involvement of the CNS may occur with encephalitis or disseminated infection and generally results in diffuse encephalitis. Disseminated infection involves multiple organ systems and can cause disseminated intravascular coagulation, hemorrhagic pneumonitis, encephalitis, and cutaneous lesions.

Diagnosis is difficult in the absence of skin lesions, which occurs in as many as 36% of cases. CSF analysis characteristically reveals elevated protein levels and mononuclear pleocytosis.

Antiviral therapy is intravenous acyclovir, 20 mg/kg every 8 hours for 14 days for skin, eye, and mouth infections and 21 days for central nervous system or disseminated disease.[16] Six months of suppressive acyclovir therapy (300 mg three times daily) can significantly improve neurologic outcome.

Even with appropriate antiviral treatment, the mortality rate for each disease classification varies from zero for skin, eye, and mouth disease to 5% for encephalitis and up to 25% for neonates with disseminated infection. In addition to this high mortality rate, children with encephalitis or disseminated disease develop normally in only 40% of cases.

346 VARICELLA-ZOSTER VIRUS (CHICKENPOX, SHINGLES)

JEFFREY COHEN

DEFINITION

Primary infection with varicella-zoster virus results in the rash of varicella (chickenpox). The varicella-zoster virus establishes a latent infection in the nervous system and can reactivate later in life to cause zoster (shingles).

The Pathogen

Varicella-zoster virus is a member of the alpha herpesvirus family and has a DNA core surrounded by a nucleocapsid, which is in turn surrounded by a viral envelope that is studded with glycoproteins. Antibody to viral glycoproteins is important for neutralizing the virus's infectivity and for protecting against primary infection. The virus encodes a thymidine kinase, which phosphorylates acyclovir, which in turn inhibits viral DNA replication by inhibiting the varicella-zoster virus DNA polymerase.

ABSTRACT

Primary infection with varicella-zoster virus results in the rash of varicella (chickenpox). The virus establishes a latent infection in the nervous system and can reactivate later in life to cause zoster (shingles). Varicella causes a disseminated rash, whereas zoster is usually a unilateral dermatomal rash in seemingly healthy persons, often at a time when their varicella-zoster virus-specific cellular immunity is impaired. Post-herpetic neuralgia, which is a dreaded complication of zoster, persists long after the rash has resolved. Acyclovir, valacyclovir, and famciclovir can treat varicella and zoster. Vaccines are approved to prevent both varicella and zoster.

KEYWORDS

varicella
chickenpox
zoster
shingles
post-herpetic neuralgia

EPIDEMIOLOGY

Before the advent of an effective vaccine, more than 95% of children in temperate climates were infected with varicella-zoster virus. By comparison, infection is usually delayed until adulthood in tropical climates. Varicella usually occurs in children younger than 5 years. Zoster is less common in tropical areas, probably because of a delay in acquisition of varicella. Varicella is more common in the winter and spring, whereas zoster has no seasonal predilection.

Primary varicella infection can occur after exposure to either chickenpox or zoster. The virus is spread by droplets and aerosols from patients or by contact with vesicular lesions. Persons are infectious beginning about 2 days before the rash appears and continuing until all lesions have crusted. Although 60 to 90% of susceptible household contacts develop varicella, only 20 to 30% of susceptible persons exposed to zoster become infected. More than 95% of primary infections result in the symptoms of varicella, and second episodes of varicella are rare. Varicella is more severe in persons with impaired cellular immunity, including patients who are infected with human immunodeficiency virus (HIV) and infants whose mothers present with varicella 5 days before to 2 days after delivery.

In unvaccinated immunocompetent adults over age 50 years, the risk of herpes zoster is about 0.9% per 100 person-years.[1] Before the introduction of an effective zoster vaccine, about 50% of persons who had varicella and lived to age 85 years developed zoster. The risk for zoster rises with increasing age (especially 50 years and older) and with increasing impairment of cellular immunity.[2,3] Perhaps because of advanced medical care and recognition by physicians, the reported incidence of zoster has increased by four-fold over the past six decades and continues to increase,[4] although hospitalizations for zoster have decreased in adults since 2008, apparently related to the herpes zoster vaccine.[5,6] Men who are infected with HIV and who are not taking antiretroviral therapies have a 15-fold higher risk for development of zoster than age-matched controls. Less than 5% of persons have a second episode of zoster, but recurrent zoster is more common in persons with impaired cellular immunity.

PATHOBIOLOGY

Varicella is transmitted by the respiratory route. The virus is thought to infect epithelial cells and lymphocytes in the oropharynx and upper respiratory tract or in the conjunctiva, and then infected lymphocytes subsequently spread the virus throughout the body. The virus then enters the skin through endothelial cells in blood vessels and spreads to epithelial cells, where it causes the vesicular rash of varicella. Lesions initially are vesicular but become pustular after the infiltration of inflammatory cells. Later the lesions break open and dry to form crusts that usually heal without scarring. During primary infection, neurons in cranial nerve ganglia and dorsal root ganglia become latently infected with the virus.[7]

If varicella-zoster virus–specific cellular immunity declines, the virus can reactivate from a ganglion, travel down the axon, and replicate in epithelial cells to cause dermatomal zoster. In highly immunocompromised persons, high-grade viremia during reactivation causes disseminated zoster.

Antibodies, which usually are present at the time varicella presents clinically, persist for life. Antibody is important for protection against varicella, as evidenced by the ability of varicella immune globulin to attenuate the disease. Cytotoxic T cells are present within 2 to 3 days after the onset of varicella and limit its severity. Varicella and zoster are more severe in persons with impaired cellular immunity (e.g., HIV infection or genetic variants, particularly variants that affect interferon function)[8] but not in patients with hypogammaglobulinemia. Cellular immunity is required to prevent reactivation of virus and zoster.

CLINICAL MANIFESTATIONS

Varicella

Varicella begins with fever and malaise followed 1 to 2 days later by a disseminated, pruritic, vesicular rash (Fig. 346-1).[9] The usual incubation period for varicella is 2 weeks (range, 10 to 21 days) after exposure to an infected person. The lesions begin as papules that become vesicles, followed by pustules and then crusts. Lesions appear on the head and then spread to the trunk and then to the extremities; the mucosa also can be involved. There are typically 200 to 500 lesions in different stages on the skin. New lesions occur for up to 5 days in normal hosts, and crusting is complete within 2 weeks.

The most common complication of varicella is bacterial superinfection of skin lesions. Group A streptococcus (Chapter 269) or *Staphylococcus aureus* (Chapter 267) infections can cause cellulitis, bacteremia, and necrotizing fasciitis. Other complications include cerebellar ataxia, viral pneumonitis, hepatitis, and thrombocytopenia. Less frequent complications include viral meningitis, encephalitis, vasculopathy (which presents as a stroke),[10] disseminated intravascular coagulopathy (Chapter 161), and Reye syndrome (more common in children receiving aspirin) (Chapter 136). Complications involving the lungs and liver are more common in children with impaired cellular immunity, including those receiving systemic steroids, children with chronic pulmonary or skin disease, adults, and pregnant women during the third trimester. The fetal varicella syndrome, which occurs in fetuses infected during the first trimester, is characterized by atrophy of limbs with scarring of skin, chorioretinitis or cataracts, and central nervous system abnormalities. HIV-infected patients who have moderately reduced CD4 cell counts may develop recurrent varicella lesions in the absence of new exposures, and patients who have CD4 cell counts below 200/μL may develop progressive varicella with new lesions occurring for at least 1 month or chronic verrucous lesions.

Zoster

In healthy persons, zoster presents with localized pain and increased sensation for 1 to 3 days before the development of a dermatomal vesicular rash that does not cross the midline (Fig. 346-2).[11] Zoster most frequently presents in the dermatomes innervated by trigeminal or thoracic ganglia. The rash is usually accompanied by itching, tingling, or pain. The lesions evolve from vesicles to pustules, and crusting is usually complete by 10 days. In normal hosts, a few lesions may develop outside of the dermatome owing to low-grade viremia. Some patients with zoster sine herpete never develop a rash.

In persons with very impaired cellular immunity, reactivation is often associated with high-grade viremia with dissemination to large areas of the skin and involvement of multiple organs. As a result, patients with underlying malignancies are more likely to develop serious complications from their zoster infections, and zoster is occasionally associated with an occult hematologic malignancy.

A dreaded complication of zoster is post-herpetic neuralgia (Chapter 26), with pain persisting for at least 1 month after the rash has resolved. Risk factors include older age and severe immunosuppression. Patients may have allodynia (sensation of pain after nonpainful stimuli), paresthesias, dysesthesias, or severe neuropathic pain. Other complications of zoster include bacterial superinfection; ocular disease, involving any of the structures of the eye, due to reactivation in the ophthalmic branch of the trigeminal ganglia; facial (Bell) palsy (Chapter 388) caused by reactivation in cranial nerve VII; Ramsay Hunt syndrome, with pain and vesicles in the ear, numbness of the anterior tongue, and ipsilateral facial palsy due to reactivation in the geniculate ganglion of

FIGURE 346-2. Dermatomal zoster. (Courtesy of Centers for Disease Control and Prevention.)

cranial nerve VII; motor neuropathy; and meningitis. Zoster vasculopathy, occurring at the time of zoster or a few months later, can present with stroke due to inflammation of the cerebral arteries.

Progressive outer retinal necrosis, with few inflammatory ocular cells, occurs when varicella-zoster virus reactivates in the eye of severely immunocompromised persons, including patients who have AIDS and low CD4 cell counts. In contrast, acute retinal necrosis with a marked inflammatory response occurs when the virus reactivates in otherwise healthy persons. Patients with AIDS or recipients of hematopoietic stem cell transplants can have pancreatitis, hepatitis, and pneumonitis in the absence of or preceding a rash. Although varicella-zoster virus antigen was reported in temporal artery biopsies of some patients with giant cell arteritis, more recent studies have failed to confirm this association.

DIAGNOSIS

Most cases of varicella and zoster are diagnosed on the basis of their clinical presentation. A disseminated vesicular rash with lesions in various stages of evolution is usually sufficient for a diagnosis of varicella. The differential diagnosis includes impetigo (Chapter 408), enterovirus infections (Chapter 349), herpes simplex (Chapter 345), Stevens-Johnson syndrome (Chapter 407), and guttate psoriasis (Chapter 405). A dermatomal vesicular rash that does not cross the midline in a patient with a prior history of pain in the area is usually diagnostic of zoster. Herpes simplex is the most common disease that resembles zoster.

When the diagnosis of varicella or zoster must be confirmed definitively, polymerase chain reaction (PCR) for varicella-zoster virus from vesicular fluid is the most sensitive and specific test.[12] PCR for varicella-zoster virus in the blood can be useful for diagnosis of visceral zoster in highly immunocompromised persons before the onset of rash. PCR for varicella-zoster virus in the cerebrospinal fluid and intrathecal synthesis of varicella-zoster virus–specific antibody is useful for diagnosis of varicella-zoster virus neurologic diseases. Culture is less sensitive than PCR because the virus is very labile. Direct fluorescent antibody testing of vesicle fluid is rapid but less sensitive than PCR. Detection of multinucleated giant cells (Tzanck smear) is less specific because lesions of herpes simplex virus have a similar appearance. Biopsy specimens show eosinophilic intranuclear inclusion bodies and multinucleate giant cells.

Serology for varicella-zoster virus is useful to determine the need for postexposure prophylaxis in persons who are at high risk for disease after exposure to varicella or zoster. Enzyme-linked immunosorbent assay tests are less sensitive than latex agglutination assays and may not detect antibodies in vaccinees.

TREATMENT

Varicella

Symptomatic treatment includes acetaminophen for fever and lotion or baths for pruritus. Although acyclovir is licensed for the treatment of varicella, the drug is not recommended for otherwise healthy children because it only modestly decreases symptoms by about 1 day.

In immunocompromised persons, intravenous acyclovir (500 mg/m^2 every 8 hours for children, 10 mg/kg every 8 hours for adults) reduces visceral dissemination and is recommended for 7 to 10 days or until all lesions have crusted. Oral acyclovir (20 mg/kg four times daily for children or 800 mg five times daily for adults) given within 24 hours after the onset of rash reduces the duration of symptoms and is recommended for treatment of adolescents, adults, newborns whose mothers developed varicella near the time of delivery, mildly immunocompromised persons, children with chronic pulmonary or skin disease, and persons with complications of varicella. Acyclovir also should be considered for household contacts of persons with varicella or for pregnant women in the third trimester; these patients often have more severe disease. Oral valacyclovir is also approved for treatment of children ages 2 years to younger than 18 years with varicella (20 mg/kg three times daily with a maximum dose of 1 g). Oral valacyclovir (1 g three times daily) or famciclovir (500 mg three times daily) results in higher antiviral drug levels than does oral acyclovir and is preferred in nonpregnant adults.

Zoster

Acyclovir, valacyclovir, and famciclovir (for 7 days at the same doses as for varicella) are licensed for the treatment of zoster.[13] Oral valacyclovir and famciclovir result in higher levels of antiviral activity than oral acyclovir does. Although therapy should be started within 3 days of the rash, therapy may still be of benefit if new lesions continue to occur after this time. Because patients younger than age 50 years usually have little pain associated with zoster, antiviral therapy is often not used in these patients unless they have moderate to severe pain, have disease involving the eye, have other complications, or are immunocompromised. Antiviral drugs (see earlier) reduce the duration of lesions and zoster-associated pain but not the incidence of post-herpetic neuralgia. In severely immunocompromised persons, intravenous acyclovir (7 to 10 days or until all lesions have crusted) reduces the risk for visceral dissemination. Oral valacyclovir or famciclovir may be used in persons who are less severely immunocompromised.

Corticosteroids (e.g., prednisone, 60 mg/day and tapered over 21 days) added to acyclovir reduce acute pain and improve the quality of life in persons older than age 50 years but do not reduce the risk for post-herpetic neuralgia. Patients with severe pain often require narcotics (see Table 26-6).

Treatment of post-herpetic neuralgia is challenging. Gabapentin (initiated at a dose of 300 mg at bedtime and titrated to a maximum dose of 1200 mg three times daily) or pregabalin (initiated at a dose of 75 mg at bedtime and titrated to a maximum dose of 300 mg twice daily) may reduce pain.[A1] Additional agents include nortriptyline (initiated at a dose of 25 mg at bedtime and titrated to a maximum dose of 150 mg daily), lidocaine patches, and topical capsaicin (which itself causes pain that is not tolerated in up to one third of patients). Opioid analgesics (see Table 26-6) may be needed but must be used cautiously because of concerns about their long-term efficacy and safety.

Treatment of Varicella-Zoster Virus Complications and Acyclovir-Resistant Varicella-Zoster Virus

Intravenous acyclovir is recommended for persons with acute retinal necrosis. Corticosteroids (e.g., prednisone, 1 mg/kg per day for 3 to 5 days) and intravenous acyclovir (10 to 15 mg/kg every 8 hours for 14 days) are recommended for nonimmunocompromised persons with varicella-zoster virus vasculopathy. Zoster involving the eye should be evaluated by an ophthalmologist to assess the potential value of topical or intraocular therapy, such as the need to reduce intraocular pressure to treat glaucoma or to use mydriatics to prevent synechiae.

Acyclovir-resistant varicella-zoster virus infections are rare and are limited almost exclusively to patients who have AIDS or are recipients of transplants. Foscarnet (40 mg/kg every 8 hours) for 2 weeks or until all lesions have crusted is the treatment of choice for acyclovir-resistant varicella-zoster virus.

PREVENTION

Varicella

Patients with varicella or zoster are considered infectious until all lesions have completely crusted. Airborne and contact precautions are recommended for varicella, whereas only contact precautions are necessary for immunocompetent persons with localized zoster.

The live attenuated varicella vaccine (Chapter 15) is recommended for children aged 1 to 12 years[A2] and for persons 13 years and older without immunity to the virus. The vaccine is 92% effective in protecting against symptomatic varicella and more than 95% effective in protecting against severe disease. Two doses of vaccine are given subcutaneously. The varicella vaccine is also given as part of a combined measles, mumps, rubella vaccine (MMRV) for children 1 to 12 years of age in the United States. The rate of disease due to varicella declined by 90% in the United States during the first 13 years after the vaccine was licensed.

The most common complications of varicella vaccination are pain at the injection site, fever, and a mild rash within 2 weeks after vaccination. The rash is often localized to the area of vaccination and is often papular; in some healthy persons, the rash can be disseminated, although there are fewer lesions and symptoms are much less severe than with wild-type virus. In persons with severely impaired cellular immunity, rash is more common, can be extensive,

and may be accompanied by organ dysfunction. The varicella vaccine establishes latency and can cause zoster, although this complication occurs less commonly with vaccine virus than with wild-type virus. The vaccine strain of varicella has been transmitted to third parties only by vaccinees who developed a rash. Varicella vaccine is contraindicated in pregnant women and persons receiving high-dose immunosuppressive therapy (e.g., ≥2 mg/kg of prednisone daily) or with hematologic malignant neoplasms. Vaccination should be considered for HIV-infected children with age-specific $CD4^+$ T cells of 15% or more and adolescents and adults with $CD4^+$ T-cell counts of 200 cells/μL or higher. Serologic testing to verify immunity is not recommended for health care workers who have received two doses of vaccine because the currently available commercial antibody assays are not sensitive enough to detect protective levels of antibody.

Zoster

Two intramuscular doses of a subunit vaccine containing varicella-zoster virus glycoprotein E and the $AS01_B$ adjuvant system (called HZ/su) is about 85% effective against herpes zoster for all age groups,[I4] with a 80% efficacy in persons age 80 years and older in clinical trials[A3] and real-world experience. This vaccine is approved by the U.S. Food and Drug Administration (FDA) and recommended by the Advisory Committee for Immunization Practices (Chapter 15) for prevention of zoster and its complications in persons 50 years of age or older, and vaccination is safe and effective even in the frail elderly.[A4] The zoster subunit vaccine is safe and immunogenic in patients with hematologic malignancies,[A5] in renal transplant recipients,[A6] and in rheumatologic patients who have autoimmune diseases but are not on immunosuppressive therapies.[A7]

A live attenuated zoster vaccine is no longer available in the United States. The zoster subunit vaccine is recommended for immunocompetent individuals who previously received the live attenuated zoster vaccine[I5] because of its improved efficacy despite more local and sometimes systemic side effects than the live attenuated vaccine.

Postexposure Prophylaxis

In persons who are exposed to varicella but who have no prior history of varicella or of vaccination, three options are available. Varicella vaccine is preferred if exposure occurred within the prior 3 days and the patient is not immunocompromised. Vaccine is estimated to be 70 to 90% effective in healthy persons. VariZIG (formerly available as varicella immune globulin) prevents or attenuates varicella in 90% of susceptible persons if it is given within 4 days of exposure. The FDA has approved VariZIG for use within 10 days of exposure, but it should be given as soon as possible after exposure. VariZIG (given intramuscularly at 125 units/10 kg body weight, up to a maximum of 625 units) is indicated for susceptible persons at risk for severe varicella (e.g., pregnant women, preterm infants, neonates whose mothers have varicella between 5 days before and 2 days after delivery, immunocompromised persons) who are in close contact with patients with varicella or zoster. VariZIG has no effect in the treatment of zoster.

Oral acyclovir (40 to 80 mg/kg daily in four divided doses for 1 week beginning 7 to 9 days after exposure) is estimated to be 80 to 85% effective as postexposure prophylaxis. It is often used when the exposure occurred too long ago for vaccination or VariZIG.

PROGNOSIS

Before vaccination, about 200 children died of varicella each year in the United States. Now varicella is the underlying cause of death in an average of less than three Americans younger than 20 years annually. Of adult patients who develop zoster, the risk of post-herpetic neuralgia (Chapter 388) is about 15 to 20%.[I6]

347 CYTOMEGALOVIRUS

GUY BOIVIN AND AJIT P. LIMAYE

DEFINITION

Cytomegalovirus (CMV) is a member of the herpesvirus family and shares, with the other members, the ability to establish a long-lived latent infection. Most of the clinical diseases caused by this virus result from reactivation of latent virus in immune-impaired patients, although primary infection in such patients can also lead to significant disease.

The Pathogen

CMV has a linear, double-stranded DNA genome with about 236,000 base pairs that encode about 167 proteins. On microscopic examination, the hallmark of tissue infection is a large (cytomegalic), 25- to 35-μm cell containing a large central, basophilic intranuclear inclusion (Fig. 347-1), referred to as an owl's eye.

EPIDEMIOLOGY

Multiple mechanisms account for the spread of this virus, including vertical (in utero, during vaginal delivery, and by breast milk) and horizontal (saliva, genital, urine, blood) contact. These routes of transmission lead, collectively, to a 15 to 20% seroprevalence by 15 years of age in developed countries, with a higher seroprevalence in lower socioeconomic settings. From that age on, there is a steady upward trend of 1 to 2% per year that is due in part to sexual transmission. As a result, approximately 50% of the general population of the United States is antibody positive by 35 years of age, and a 1% per year rate of increase occurs thereafter. In underdeveloped countries, up to 90% of persons may be seropositive by 2 years of age.[1] Presumably, crowded living conditions permit spread of the virus through close contact with body fluids. A study showed that CMV was viable on metal and wood for up to 1 hour, glass and plastic up to 3 hours, and rubber, cloth, and crackers up to 6 hours. CMV was more likely to be isolated from wet, highly absorbent surfaces. These considerations were felt to be particularly important because children may actively shed CMV in saliva and urine for months to years, and exposure to bodily fluids

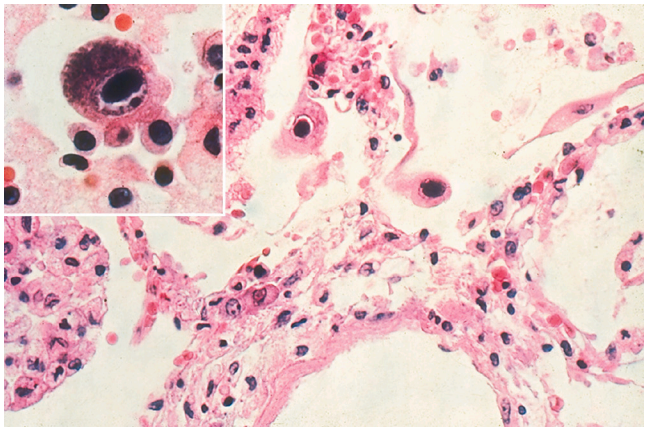

FIGURE 347-1. Cytomegalovirus (CMV) pneumonia. A lung biopsy specimen was stained with hematoxylin and eosin and magnified 250-fold. The *inset* shows a CMV "owl's eye" inclusion.

and may be accompanied by organ dysfunction. The varicella vaccine establishes latency and can cause zoster, although this complication occurs less commonly with vaccine virus than with wild-type virus. The vaccine strain of varicella has been transmitted to third parties only by vaccinees who developed a rash. Varicella vaccine is contraindicated in pregnant women and persons receiving high-dose immunosuppressive therapy (e.g., ≥2 mg/kg of prednisone daily) or with hematologic malignant neoplasms. Vaccination should be considered for HIV-infected children with age-specific $CD4^+$ T cells of 15% or more and adolescents and adults with $CD4^+$ T-cell counts of 200 cells/μL or higher. Serologic testing to verify immunity is not recommended for health care workers who have received two doses of vaccine because the currently available commercial antibody assays are not sensitive enough to detect protective levels of antibody.

Zoster

Two intramuscular doses of a subunit vaccine containing varicella-zoster virus glycoprotein E and the $AS01_B$ adjuvant system (called HZ/su) is about 85% effective against herpes zoster for all age groups,[I4] with a 80% efficacy in persons age 80 years and older in clinical trials[A3] and real-world experience. This vaccine is approved by the U.S. Food and Drug Administration (FDA) and recommended by the Advisory Committee for Immunization Practices (Chapter 15) for prevention of zoster and its complications in persons 50 years of age or older, and vaccination is safe and effective even in the frail elderly.[A4] The zoster subunit vaccine is safe and immunogenic in patients with hematologic malignancies,[A5] in renal transplant recipients,[A6] and in rheumatologic patients who have autoimmune diseases but are not on immunosuppressive therapies.[A7]

A live attenuated zoster vaccine is no longer available in the United States. The zoster subunit vaccine is recommended for immunocompetent individuals who previously received the live attenuated zoster vaccine[I5] because of its improved efficacy despite more local and sometimes systemic side effects than the live attenuated vaccine.

Postexposure Prophylaxis

In persons who are exposed to varicella but who have no prior history of varicella or of vaccination, three options are available. Varicella vaccine is preferred if exposure occurred within the prior 3 days and the patient is not immunocompromised. Vaccine is estimated to be 70 to 90% effective in healthy persons. VariZIG (formerly available as varicella immune globulin) prevents or attenuates varicella in 90% of susceptible persons if it is given within 4 days of exposure. The FDA has approved VariZIG for use within 10 days of exposure, but it should be given as soon as possible after exposure. VariZIG (given intramuscularly at 125 units/10 kg body weight, up to a maximum of 625 units) is indicated for susceptible persons at risk for severe varicella (e.g., pregnant women, preterm infants, neonates whose mothers have varicella between 5 days before and 2 days after delivery, immunocompromised persons) who are in close contact with patients with varicella or zoster. VariZIG has no effect in the treatment of zoster.

Oral acyclovir (40 to 80 mg/kg daily in four divided doses for 1 week beginning 7 to 9 days after exposure) is estimated to be 80 to 85% effective as postexposure prophylaxis. It is often used when the exposure occurred too long ago for vaccination or VariZIG.

PROGNOSIS

Before vaccination, about 200 children died of varicella each year in the United States. Now varicella is the underlying cause of death in an average of less than three Americans younger than 20 years annually. Of adult patients who develop zoster, the risk of post-herpetic neuralgia (Chapter 388) is about 15 to 20%.[I6]

347 CYTOMEGALOVIRUS

GUY BOIVIN AND AJIT P. LIMAYE

DEFINITION

Cytomegalovirus (CMV) is a member of the herpesvirus family and shares, with the other members, the ability to establish a long-lived latent infection. Most of the clinical diseases caused by this virus result from reactivation of latent virus in immune-impaired patients, although primary infection in such patients can also lead to significant disease.

The Pathogen

CMV has a linear, double-stranded DNA genome with about 236,000 base pairs that encode about 167 proteins. On microscopic examination, the hallmark of tissue infection is a large (cytomegalic), 25- to 35-μm cell containing a large central, basophilic intranuclear inclusion (Fig. 347-1), referred to as an owl's eye.

EPIDEMIOLOGY

Multiple mechanisms account for the spread of this virus, including vertical (in utero, during vaginal delivery, and by breast milk) and horizontal (saliva, genital, urine, blood) contact. These routes of transmission lead, collectively, to a 15 to 20% seroprevalence by 15 years of age in developed countries, with a higher seroprevalence in lower socioeconomic settings. From that age on, there is a steady upward trend of 1 to 2% per year that is due in part to sexual transmission. As a result, approximately 50% of the general population of the United States is antibody positive by 35 years of age, and a 1% per year rate of increase occurs thereafter. In underdeveloped countries, up to 90% of persons may be seropositive by 2 years of age.[1] Presumably, crowded living conditions permit spread of the virus through close contact with body fluids. A study showed that CMV was viable on metal and wood for up to 1 hour, glass and plastic up to 3 hours, and rubber, cloth, and crackers up to 6 hours. CMV was more likely to be isolated from wet, highly absorbent surfaces. These considerations were felt to be particularly important because children may actively shed CMV in saliva and urine for months to years, and exposure to bodily fluids

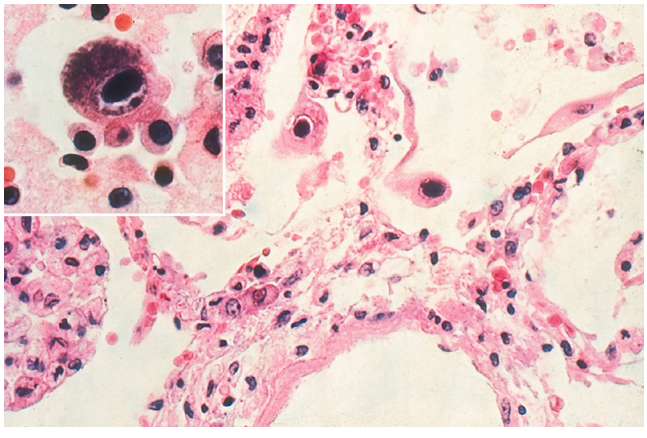

FIGURE 347-1. Cytomegalovirus (CMV) pneumonia. A lung biopsy specimen was stained with hematoxylin and eosin and magnified 250-fold. The *inset* shows a CMV "owl's eye" inclusion.

ABSTRACT

Cytomegalovirus (CMV) belongs to the Herpesviridae family. The seroprevalence of CMV is estimated to be 50% by adulthood. CMV establishes latency in host cells and may reactivate. CMV infections are generally asymptomatic in immunocompetent individuals or may be associated with mononucleosis-like syndromes. Clinical diseases result from reactivation of latent virus, primary infection or reinfections in immunocompromised patients such as transplant recipients and patients with advanced human immunodeficiency virus (HIV) infection. The virus is excreted in most biological fluids and may be transmitted through vertical and horizontal routes. Congenital infection may either be asymptomatic or lead to microcephaly, intracerebral calcifications, hepatosplenomegaly, and rash in 10% of newborns excreting CMV. Half of the survivors will develop hearing loss and/or intellectual disability. Clinical manifestations in immunocompromised hosts include a nonspecific viral illness termed "CMV syndrome" or diseases such as retinitis, pneumonitis, colitis, hepatitis, pancreatitis, and meningoencephalitis. CMV infections may increase the risks of bacterial infections and invasive fungal infections, reactivation of other herpesviruses, immunosenescence, acute or chronic allograft rejection, graft loss, and death. Diagnosis of CMV infection is performed by viral DNA quantification on whole blood, plasma, or other fluids or tissues by PCR. Candidate vaccines are being developed but remain experimental. Prophylaxis or preemptive therapy with antivirals is commonly administered to transplant recipients to prevent CMV infections and diseases. First-line antiviral therapy, which targets the viral DNA polymerase, includes ganciclovir and its prodrug valganciclovir, whereas second-line agents include foscarnet, cidofovir, and maribavir. Letermovir, a viral terminase inhibitor, is used for prophylaxis in recipients of stem cell transplants and is under study in recipients of kidney transplants.

from young children poses substantial risk for CMV exposure among women of reproductive age. Two additional mechanisms of transmission are blood transfusion and organ transplantation. A final important epidemiologic fact is that reinfection with a different strain of CMV may occur in CMV-seropositive persons, especially those who are immunocompromised or pregnant or have multiple sexual partners.

PATHOBIOLOGY

In immunocompetent individuals, CMV rarely causes clinically evident end-organ disease. When immune mechanisms are deficient, especially mechanisms mediated by $CD4^+$ and $CD8^+$ lymphocytes, latent virus replicates and causes both direct and indirect effects. Examples of direct virally mediated diseases are necrotizing CMV retinitis and esophagitis. In contrast, CMV pneumonitis is frequently manifested as subtle histologic alterations accompanied by limited viral replication, thereby suggesting that immune-mediated injury may be the primary pathologic mechanism.[2] Such injury may result from the upregulation and release of cytokines, including tumor necrosis factor-α, interferon-γ, and interleukin-2. Immune-mediated tissue injury may also be effected by $CD8^+$ cytotoxic T lymphocytes directed against CMV-infected target cells. The clinical manifestations of CMV infection, including meningoencephalitis, retinitis, enteritis, vasculitis, pneumonitis, myocarditis, lymphadenitis, hepatitis, adrenalitis, and pancreatitis, reflect the range of cell types that CMV is capable of infecting. The indirect effects of CMV include increased risks of some bacterial infections and invasive fungal diseases, reactivation of other herpesviruses, immunosenescence, rejection, graft loss, and death.

The immune response to CMV infection involves both the humoral and cell-mediated arms, and T-cell responses appear to be the most important for controlling reactivated infection. The CMV envelope glycoproteins that participate in viral entry are gB, gH/gL, and gCII, as components of the pentameric complex. Humoral immunity directed at gB has been detected in convalescent phase sera and has been shown to block viral entry, cell-to-cell transmission, and syncytium formation in CMV-infected cells. Not surprisingly, components of the pentameric complex are the primary target of experimental vaccines.

Fundamental to the pathogenesis of CMV is latency, or persistence of the viral genome in host cells without evidence of productive viral replication. It is thought that monocytes and bone marrow progenitor cells are sites of human CMV latency. Reactivation from latency has classically been associated with immunosuppression. Exposure to a rich milieu of cytokines and growth factors results in the activation of signal transduction pathways, generation of increased levels of intracellular transcription factors, and production of viable virus.

CLINICAL MANIFESTATIONS

Congenital and Neonatal Infection

In the developed world, congenital infection occurs in approximately 0.2 to 0.7% of newborns. Thus, in the United States, each year approximately 40,000 infants are born excreting CMV, and about 4000 (or ~10%) of these newborns show clinical evidence of congenital disease, such as microcephaly, intracerebral calcification, hepatosplenomegaly, and rash.[3] About 90% of these clinically infected newborns will survive, but half of the survivors will have unilateral or bilateral hearing loss, developmental delay, or both. Mothers of most infants with symptomatic CMV infection had a primary infection during pregnancy, although it is now well known that clinically evident congenital infection also occurs in infants born to mothers with past CMV infection. In mothers with a primary infection, a negative amniocentesis markedly reduces the likelihood of hearing impairment and makes more serious sequelae very unlikely. In newborns who are born to women with primary CMV infection but are initially asymptomatic, a higher viral load may increase the risk for subsequent CMV-related sequelae. Up to 14% of asymptomatic infected babies at birth will eventually develop learning problems or hearing loss.

Infection in Immunocompetent Persons

Virtually all CMV infections occurring in immunocompetent persons are asymptomatic. In some patients, a clinical illness resembling infectious mononucleosis may develop (Chapter 348), but with minimal pharyngitis and lymphadenopathy. Atypical lymphocytosis develops in these patients, similar to Epstein-Barr virus infection, but they have a negative heterophil antibody test result. Thrombocytopenia is an occasional complication.[4] CMV reactivation is more common in elderly and frail individuals and is especially common (33%) in critically ill immunocompetent patients, in whom it is associated with prolonged hospitalization and mortality, but whether it causes these effects is unclear.[5]

Infection in Transplant Recipients

When a CMV-seronegative recipient receives a solid organ from a CMV-seropositive donor, the resulting illnesses include the "CMV syndrome," characterized by fever, neutropenia, atypical lymphocytes, and sometimes by hepatosplenomegaly.[6] CMV disease may also develop in the transplanted organ. For example, CMV hepatitis in liver transplant recipients is associated with fever, hyperbilirubinemia, and elevated liver enzymes; liver failure may ensue and necessitate retransplantation. Recipients of a solid organ transplant may develop CMV disease by reactivation of latent infection, reinfection by an exogenous strain, or transmission of CMV from a seropositive donor to a seronegative individual (primary infection).[7] Disease in CMV-seropositive recipients is, fortunately, less severe than that resulting from primary infection. CMV infection occurs more commonly in recipients of lung or liver transplants than in recipients of kidney transplants.

CMV pneumonia may occur after solid organ transplantation but is most common after stem cell transplantation.[8] Fever, nonproductive cough, and dyspnea can progress rapidly. The diagnosis is suggested by interstitial to nodular infiltrates rather than by alveolar densities on chest radiographs. In contrast to solid organ transplantation, CMV disease after stem cell transplantation usually results from reactivation of latent CMV in a seropositive recipient rather than from a new, primary infection.

CMV may cause disease throughout the gastrointestinal tract. Colitis, which is a common syndrome in transplant recipients, is manifested as diarrhea, weight loss, and fever. It is characterized by diffuse submucosal hemorrhages and ulcerations.

Infection in Patients with Acquired Immunodeficiency Syndrome

In the era before highly active antiretroviral therapy, CMV retinitis occurred in approximately one third of patients with acquired immunodeficiency syndrome (AIDS), most often in those with CD4 counts below 50/μL. It usually begins unilaterally with visual blurring, floaters, decreased acuity, and loss of visual fields and progresses to blindness if it is untreated. The retinal examination is abnormal, and the finding of apparent hemorrhages and exudates is the best diagnostic test (Fig. 347-2). CMV colitis is similar to that seen in transplant recipients, but esophagitis is also common and characterized by distal ulceration, which may be single but extensive.

CMV neurologic disease occurs in multiple forms, including encephalitis and a polyradiculopathy/myelitis syndrome. The encephalitis, which usually occurs only in patients who are profoundly immunosuppressed, typically presents as a subacute encephalopathy with headache, impaired cognition, apathy, and social withdrawal. CMV transverse myelitis is indistinguishable neurologically from other forms of transverse myelitis (Chapters 369 and 380). In human immunodeficiency virus (HIV)–infected patients, CMV polyradiculomyelitis

FIGURE 347-2. Cytomegalovirus retinitis as seen by direct ophthalmoscopic examination.

presents subacutely over days to weeks with paresthesias or dysesthesias that rapidly progress to paraparesis with hypotonia.

With the efficacy of combination antiretroviral therapy, the incidence of all of these CMV syndromes has decreased dramatically, but they are still seen before HIV treatment or when such treatment is interrupted or ineffective.

Even in the current era of HIV treatment, evidence of immunoglobulin G–positive CMV infection is associated with an increased risk of severe non–AIDS-defining events and non–AIDS-related death, especially cardiovascular and cerebrovascular events, thereby suggesting a role for CMV coinfection in vascular/degenerative organ disorders in HIV-infected patients.[9]

DIAGNOSIS

Assay of viral DNA by polymerase chain reaction (PCR) testing is more sensitive than viral culture and is the best assay for the early detection of CMV disease. This assay, mainly performed on whole blood or plasma, can provide quantification that is especially helpful in supporting the diagnosis of CMV disease, enacting preemptive antiviral intervention, and monitoring therapy. PCR detection of CMV in cerebrospinal fluid is the preferred diagnostic approach to patients with suspected CMV neurologic disease. Monoclonal antibodies can quantify viremia by counting CMV antigen–positive cells directly in peripheral blood leukocytes (antigenemia). Viral culture is rarely used clinically, and culture-positivity does not prove causality, especially in immunocompromised patients. Cytologic and histologic abnormalities are not sensitive measures of CMV infection, but they are specific indicators of CMV disease.

TREATMENT

The Medications

Oral valganciclovir, intravenous ganciclovir, intravenous ganciclovir followed by oral valganciclovir, oral maribavir, intravenous foscarnet, intravenous cidofovir, and ganciclovir intraocular injection coupled with valganciclovir are all effective treatments of established CMV diseases (Table 347-1).[10] These drugs (especially ganciclovir/valganciclovir) also can be used preemptively (i.e., when the viral load reaches a predetermined level even before the development of clinical disease).[A1]

TABLE 347-1 TREATMENT OF CYTOMEGALOVIRUS DISEASE

	PREFERRED THERAPY	ALTERNATIVE THERAPY
Cytomegalovirus (CMV) retinitis* Sight-threatening lesions	Valganciclovir 900 mg bid PO ± ganciclovir intraocular injection	Ganciclovir IV; foscarnet IV; plus ganciclovir intraocular injection
Peripheral lesions	Valganciclovir 900 mg bid PO	Ganciclovir IV or foscarnet IV
Maintenance therapy	Valganciclovir 900 mg qd PO	Ganciclovir IV or foscarnet IV
CMV gastrointestinal disease	Ganciclovir IV for 3-6 wk or valganciclovir 900 mg bid PO for 3-6 wk	Foscarnet IV for 3-6 wk
CMV neurologic disease	Ganciclovir IV + foscarnet IV	
CMV viremia syndrome	Valganciclovir 900 mg bid PO or ganciclovir IV until viremia clears	Foscarnet IV
Ganciclovir resistant	Foscarnet IV ± IV ganciclovir, and intraocular injection	Maribavir or cidofovir (if only *UL97* mutation)

*If not already begun, antiretroviral therapy should be initiated concurrently with anti-CMV therapy, except possibly when treating central nervous system disease. For retinitis, anti-CMV therapy should be continued until the CD4 count has exceeded 100-150 cells/μL for ≥6 months and the retinitis is inactive. If anti-CMV therapy is discontinued, regular monthly eye examinations should be continued. Early relapses of CMV retinitis in patients treated systemically are usually due to inadequate drug penetration, and reinduction with the same drug is often effective. Drug resistance may occur in patients treated for ≥3 months. Therapy of these patients may be guided by genotyping.
bid = twice daily; IV = intravenously; PO = orally; qd = once daily.
Adapted from Drew WL, Erlich KS. Management of herpesvirus infections (cytomegalovirus, herpes simplex virus, and varicella-zoster virus). In: Volberding PA, Greene WC, Lange J, et al., eds. *HIV/AIDS Medicine Medical Management of AIDS 2012*. Philadelphia: Saunders Elsevier; 2012:433.

Ganciclovir is a nucleoside analogue given intravenously, 5 mg/kg two times daily during initial induction (2 to 3 weeks); maintenance therapy consists of 5 mg/kg once daily (Chapter 328). Ganciclovir resistance may occur as a result of mutations in the protein kinase gene (*UL97*) and/or in the DNA polymerase gene (*UL54*). Granulocyte colony-stimulating factor may be needed to offset neutropenia. Valganciclovir (an oral prodrug of ganciclovir) achieves levels comparable to intravenous ganciclovir at 5 mg/kg when it is given orally in a 900-mg dose, two times daily, and is followed by 900 mg once daily as a maintenance dose.

Foscarnet blocks the pyrophosphate-binding site of viral DNA polymerase, thereby preventing cleavage of pyrophosphate from deoxynucleotide triphosphate. The recommended initial therapy with foscarnet is 60 mg/kg intravenously every 8 hours or 90 mg/kg every 12 hours. The maintenance dose ranges from 90 to 120 mg/kg daily. Adverse effects include renal impairment, anemia, hypocalcemia (especially ionized calcium), hypomagnesemia, and hypophosphatemia. Resistance to foscarnet can develop because of mutations in the DNA polymerase gene. Although it is effective for treating CMV retinitis, its toxicity and the absence of an oral formulation make foscarnet a second choice for treatment of CMV disease.

Cidofovir is a nucleotide analogue that is active against ganciclovir-resistant CMV strains with resistance mutations only in *UL97*. The drug's extremely long half-life permits intravenous administration as infrequently as every 2 weeks during maintenance treatment. However, cidofovir is nephrotoxic, especially to the proximal renal tubule, and its toxicities make it a second- or third-line agent for treatment of CMV. Maribavir (400 mg twice daily), which inhibits the UL97 protein kinase of CMV, is effective[A2] and approved for recipients of hematopoietic or solid organ transplants who do not respond to other agents.[11] Letermovir is useful only for prevention but not treatment of established CMV infection.

Retinitis

For CMV retinitis, approximately 75% of patients treated with ganciclovir or valganciclovir respond with improvement or stabilization of vision or ophthalmoscopic appearance. CMV retinitis also can be treated locally by intraocular ganciclovir injection, but this approach should be accompanied by oral valganciclovir to treat and/or prevent extraocular end-organ disease.

Neurologic Disease

For neurologic disease, ganciclovir (5 mg/kg intravenously every 12 hours) plus foscarnet (60 mg/kg intravenously every 8 hours or 90 mg/kg intravenously every 12 hours until symptomatic improvement) is usually recommended, followed by maintenance therapy with oral valganciclovir (900 mg daily) and intravenous foscarnet (90 to 120 mg/kg intravenously during 2 hours, every 24 hours). Cidofovir is a second-line agent (5 mg/kg by intravenous infusion during 1 hour once a week for 2 consecutive weeks, with saline hydration and probenecid, 2 g orally 3 hours before the dose and 1 g orally at 2 hours and 8 hours after the dose). A maintenance dose of 5 mg/kg every other week is recommended unless and until immune reconstitution occurs. Additionally, HIV-specific antiviral therapy must be given to facilitate immune control of CMV. However, clinical deterioration due to inflammatory immune reconstitution syndrome (Chapter 357) may occur and must be closely monitored.

Post-Transplant CMV

Ganciclovir together with CMV hyperimmune globulin may reduce the mortality of CMV pneumonia after stem cell transplantation from approximately 85 to 40%, although the benefit of the antibody is unproved.

PREVENTION

Multiple vaccine approaches are being investigated to prevent or to mitigate CMV-associated complications.[12] Additionally, passive immunity (monoclonal antibodies) to pentameric complex also is being studied in high-risk transplant settings.

Because CMV is transmitted by exchange of secretions, infection can be diminished by reducing exposure to body fluids. For example, transmission by both vaginal and anal intercourse, which poses bidirectional risks, can be diminished by use of condoms. Similarly, limiting the contact of seronegative pregnant women with the secretions and excretions of children, especially preschoolers in daycare, can decrease primary infection and, in turn, congenital disease. The risk for acquiring CMV disease can be reduced in seronegative, immunosuppressed patients by using blood products or organ grafts only from CMV-seronegative donors or apheresis blood products.

Valganciclovir and ganciclovir, in the same doses used for treatment, provide effective prophylaxis in solid organ transplantation,[13] and either one is commonly administered for a 3- to 6-month period after transplantation.[A3] However, late-onset CMV end-organ disease may occur when the antiviral drug is eventually discontinued.

Prophylaxis has been uncommon for stem cell transplant recipients,[14] and these patients typically have been monitored weekly (from day 10 to day 100 after transplantation) for CMV DNA or antigenemia, with antiviral therapy

introduced preemptively if viremia occurs.[A4] With this strategy, infection is not prevented, but end-organ disease is avoided. Letermovir (a CMV terminase inhibitor 240 or 480 mg daily) can reduce the incidence of CMV infection in such patients,[A5,A6] and is replacing valganciclovir for the prevention of CMV infection and disease.[15,16] CMV hyperimmune globulin can be used prophylactically in high-risk seronegative organ transplant recipients, in whom it reduces CMV disease and mortality. It is very expensive, however, and antivirals are more commonly used alternatives.

For the prevention of vertical transmission of CMV after maternal primary infection during the first trimester of pregnancy, valacyclovir (8 g per day) may be effective in reducing the rate of fetal CMV infection by about 70%.[A7] By comparison, CMV-specific hyperimmune globulin is not effective in this setting.[A8]

PROGNOSIS

In immunocompetent patients, the mononucleosis-like CMV syndrome resolves spontaneously, and prior infection is not associated with all-cause mortality.[17] Infections in immunocompromised patients are much more serious, and patients with homozygous nitric oxide synthase 2 deficiency may have fatal primary infection.[18] CMV infection also may result in failure of a transplanted solid organ and/or systemic CMV disease. For CMV pneumonia, death often occurs even with antiviral therapy, especially after stem cell transplantation. In AIDS patients, CMV infection generally resolves when CD4 counts exceed 100/μL, but it is a grave prognostic sign if counts do not recover to those levels.

348 EPSTEIN-BARR VIRUS INFECTION

ROBERT T. SCHOOLEY AND UPTON D. ALLEN

DEFINITION

Epstein-Barr virus (EBV), a member of the gamma human herpesvirus family, is the etiologic agent of infectious mononucleosis and of a diverse assortment of neoplastic and lymphoproliferative syndromes.

EPIDEMIOLOGY

Ubiquitous in the human population, EBV is found in 90 to 95% of adults throughout the world. As in the case of other herpesviruses, infection with EBV is lifelong. The virus resides in B lymphocytes and is intermittently shed asymptomatically in oropharyngeal secretions, which accounts for the bulk of its transmission in the human population. The virus is usually acquired during early childhood by sharing of saliva-bearing fomites or during adolescence by kissing, although it can be acquired at any decade of life. In addition to oropharyngeal spread, the virus can be transmitted by blood transfusion or by organ and tissue donation.

Most childhood EBV infections are clinically silent, but infection of adolescents and adults results in the clinical syndrome of infectious mononucleosis between 25 and 50% of the time, depending on the setting. The incidence of infectious mononucleosis is highest in the 15- to 24-year-old age group. Incidence rates in men and women are equal, but the peak incidence is 2 years earlier in women than in men. Incidence rates are lower in lower socioeconomic populations, due to the likelihood of acquisition of EBV during early childhood rather than during adolescence.

PATHOBIOLOGY

EBV infects B lymphocytes preferentially but also infects epithelial cells. For B lymphocytes, the receptor is CD21, whereas for epithelial cells, cellular entry is less well defined. Infection of B cells typically results in two pathways: lytic destruction of B lymphocytes owing to viral replication, and latency within lymphocytes. Once inside the cell, the virus expresses several nuclear proteins (termed *Epstein-Barr nuclear antigens* [EBNAs]) that activate EBV-encoded latent membrane proteins and other gene products responsible for regulation of B-cell growth. These events are associated with the transformation or immortalization of the B cell that is the phenotypic hallmark of B-cell infection.[1] EBV-transformed B cells have the potential to proliferate vigorously but are prevented from doing so in the normal host due to surveillance by T lymphocytes.

The host response to acute EBV infection consists of a vigorous and coordinated cellular and humoral immune response. The humoral immune response includes IgM and IgG antibodies directed at the viral capsid (VCA) and to EBNA, as well as "heterophile" antibodies to surface antigens of sheep red blood cells. Heterophile antibodies are useful diagnostically and are present at some point in up to 90% of adolescents and adult cases but are often not detected in children younger than 4 years of age. These antibodies are an epiphenomenon in host defense and are not cross-reactive with any known viral antigens.

The cellular immune response includes both natural killer and EBV-specific $CD4^+$ and $CD8^+$ T lymphocytes. The expansion of the $CD8^+$ subset of T lymphocytes during acute EBV infection includes a subset of large, activated cells demonstrable on standard peripheral blood smears as "atypical" lymphocytes. This vigorous cellular immune response is associated with an outpouring of cytokines, including tumor necrosis factor, interleukin-1, and interleukin-6, that are responsible for many of the symptoms and signs of infectious mononucleosis. Over a period of 4 to 6 weeks after initial evaluation in most patients, adaptive immune mechanisms gain control of the EBV-driven B-cell proliferation and the virus enters into a lifelong period of symbiosis with the host. The virus is asymptomatically shed in the oropharyngeal fluids of healthy human immunodeficiency virus type 1 (HIV-1)–seronegative adolescents and adults and is shed even more often in individuals with T-cell defects, such as occur with HIV-1 infection or immunosuppression associated with organ allografts. Shedding is increased among healthy persons during periods of transient immune dysregulation.

ACUTE INFECTION

CLINICAL MANIFESTATIONS

Most cases of acute EBV infection are clinically silent. The syndrome of infectious mononucleosis consists of the clinical triad of fever, sore throat (Chapter 397),[2] and lymphadenopathy, in association with an atypical lymphocytosis[3] (Fig. 348-1) and the transient appearance of heterophile antibodies.

The incubation period between exposure and the onset of symptoms is generally 30 to 50 days. The onset of symptoms may be abrupt, or it may be heralded by a several-day nonspecific prodrome of malaise and low-grade fever. Although the classic syndrome includes fever, sore throat, and adenopathy, the findings may be dominated by only one or any combination of these symptoms. Other common clinical manifestations include headache, malaise, and anorexia. On physical examination, patients are usually febrile. Pharyngeal erythema, tonsillar enlargement (see Fig. 397-4 in Chapter 397), and cervical adenopathy are generally present. Mild periorbital edema may also be observed. Abdominal findings may include splenomegaly or hepatomegaly, or both. Splenomegaly can be demonstrated by ultrasonographic examination in virtually all patients with infectious mononucleosis, although palpable splenomegaly is present in only about 20% of patients. Splenic enlargement is usually maximal in

the second or third week of illness and might not be detectable at the initial presentation. Adenopathy may be observed in noncervical regions, but it is usually much less prominent than in cervical regions.

More serious primary infections can occur in individuals over age 30 years. Approximately 5% of patients will exhibit a rash that may be macular, scarlatiniform, or urticarial in nature. Ampicillin or its derivatives evoke a pruritic maculopapular eruption in 15 to 30% of patients with acute EBV infection in recent series, compared with a reported 80 to 100% in earlier reports. Patients with an ampicillin-induced rash during acute EBV infection generally tolerate the drug and other penicillin products when administered later in life.

Complications

Most patients have self-limited disease EBV, but a number of complications may arise. In some patients, these complications dominate the clinical findings, and seroconversion to EBV may be the only evidence of acute EBV infection.

Patients should be specifically warned about splenic rupture, a complication attributable to splenomegaly (Chapter 154) and associated stretching of the splenic capsule that occurs most frequently in the second or third week of the illness, when other symptoms of the disease are abating. It may be accompanied by trauma but may also occur without an obvious antecedent event. Left upper quadrant pain, especially pain radiating to the subscapular region, should raise this diagnostic consideration. As with other complications of acute EBV infection, splenic rupture may occur occasionally in patients without other prominent clinical manifestations of acute EBV infection. Other hematologic complications, which usually arise from a combination of self-reactive antibodies and hypersplenism, include autoimmune hemolytic anemia (Chapter 146), thrombocytopenia (Chapter 158), and neutropenia (Chapter 153).

Neurologic complications can also occur during acute EBV infection. EBV DNA has been detected in brain tissue from rare patients with clinical manifestations compatible with herpes simplex encephalitis (Chapter 383). Other neurologic complications include aseptic meningitis (Chapter 381), cerebellitis, mononeuritis multiplex (Chapter 388), Bell palsy (Chapter 388), Guillain-Barré syndrome (Chapter 388), transverse myelitis (Chapters 369 and 380), and a higher risk of multiple sclerosis.[4]

Mild hepatomegaly is common in acute infectious mononucleosis, and biochemical evidence of hepatitis (Chapter 134) is to be expected in virtually every case of acute infection. More severe hepatic complications are uncommon, however. Renal, cardiac, pulmonary, and skeletal muscle complications are rare.

X-Linked Lymphoproliferative Syndrome

The most serious complication of acute EBV infection arises in individuals with the X-linked lymphoproliferative syndrome. This syndrome occurs in males with mutations in the signaling lymphocyte activation molecule (SLAM)–associated protein (SAP) that regulates T-cells and natural killer (NK) cells. These previously healthy individuals who become immune dysregulated upon encountering EBV have severe clinical symptoms, a pronounced lymphocytosis consisting of T and B cells, and severe hepatitis. If patients survive the acute infection, the syndrome may evolve into progressive agammaglobulinemia or lymphoma in the following months. The genetic defect associated with this syndrome can be diagnosed in utero, and early bone marrow transplantation has been recommended for the prevention of the devastating clinical syndrome associated with the acquisition of EBV infection.

DIAGNOSIS

Because clinical manifestations of acute EBV infection are variable and other organisms may cause similar clinical syndromes, laboratory tools are required to confirm an etiologic diagnosis. Heterophile antibodies to sheep red blood cells are classically used to diagnose EBV-induced infectious mononucleosis. Although ultimately demonstrable in approximately 90% of symptomatic acute EBV infections, these antibodies are present in only about two thirds of patients at initial encounter. If antibodies are negative at the outset and clinical suspicion is high, repeat testing in the second or third week of the illness is warranted. EBV-specific antibodies remain the "gold standard" for the diagnosis of acute EBV infection, but if heterophile antibodies are demonstrated in a straightforward case of infectious mononucleosis, EBV-specific serologic studies are not generally required. Testing for IgM antibodies to the EBV capsid antigen (VCA) is the most useful serologic study in the diagnosis of acute EBV infection. Relatively high titers of IgG antibodies to VCA persist for life after initial infection and are not useful in making the diagnosis of acute EBV infection. Antibodies to EBNA are slower to arise than those to capsid antigens, and acute infection may be diagnosed by demonstration of seroconversion to this antigen.

Among pathogens causing clinical syndromes that can be mistaken for acute EBV infection, cytomegalovirus (Chapter 347) is the most frequent. Patients with cytomegalovirus infection are less likely to have an acute onset of illness, and pharyngitis is less frequently a prominent manifestation of the illness. *Toxoplasma gondii* (Chapter 320) infection can also present as a nonspecific febrile illness that can be confused with infectious mononucleosis. Streptococcal pharyngitis (Chapter 269), primary herpes stomatitis (Chapter 345), and adenovirus infection (Chapter 333) may occasionally cause symptoms that are mistaken for acute EBV infection. None of these syndromes is associated with heterophile antibodies or with other serologic evidence of acute EBV infection. The differential diagnosis is generally made by serologic studies directed at these organisms or by culture. Nonetheless, physicians should be cognizant that organisms such as group A β-hemolytic streptococci (Chapter 269) and herpes simplex virus are also common in the human population and may be demonstrated in people whose symptoms are nonetheless due to acute EBV infection.

TREATMENT AND PREVENTION

The clinical course is generally self-limited and does not usually require specific therapeutic intervention beyond the use of aspirin or acetaminophen for antipyresis and mild pain relief, except in the presence of specific complications such as when lymphadenopathy threatens the airway or in certain cases of autoimmune hemolytic anemia (Chapter 146) or thrombocytopenia (Chapter 158). To reduce the risk of splenic rupture, patients should be counseled against activities that might result in abdominal trauma for 6 to 8 weeks after the onset of symptoms.

Short courses of corticosteroids have been used to hasten symptomatic recovery in cases in which the symptoms are severe or refractory.[A1] For example, corticosteroids may be of benefit in more severe cases of autoimmune hemolytic anemia (Chapter 146) or thrombocytopenia (Chapter 158). Corticosteroids should not, however, be used routinely and should consist of no more than a 10- to 14-day tapering course that begins at a dose equivalent to 0.5 to 1 mg/kg of prednisone. Although EBV replication can be inhibited in vitro or in vivo by acyclovir and related antiviral agents, the symptoms of infectious mononucleosis are primarily driven by the immune response to the virus and follow the time of maximal viral replication. Antiviral agents have not been demonstrated to accelerate resolution of symptoms significantly or prevent complications of the disease.[A2] However, patients with encephalitis may be treated with parenteral ganciclovir (10 mg/kg/day intravenously for 3 weeks followed by valganciclovir 900 mg/day orally for another 3 weeks until the virus is cleared; Chapter 328).

Because the virus is usually transmitted by asymptomatic oral shedders and is so common in the human population, epidemiologic interventions directed at patients with acute infection are not warranted to prevent spread. No vaccine yet has been developed for clinical use.

PROGNOSIS

Most patients recover uneventfully from the acute symptoms and signs of infectious mononucleosis over a 2- to 3-week period, although many patients may have a variable period of malaise and fatigue that can last for another 3 to 4 weeks. Some patients may take longer to make a full recovery and experience fatigue and difficulty concentrating for up to 6 months after diagnosis. Symptoms often wax and wane and can be extremely troublesome. Reassurance is usually the best approach to these patients. Corticosteroids are not of benefit in this setting.

Recovery may be less straightforward in patients with certain specific complications of acute EBV infection. Hematologic complications are generally self-limited and resolve with the resolution of the illness. Neurologic complications may be clinically dramatic but are usually self-limited and associated with full recovery in 85% of patients without specific antiviral therapy.

Death from infectious mononucleosis is rare. When it does occur, it is most frequently associated with neurologic complications, splenic rupture, or the X-linked lymphoproliferative syndrome.

OTHER CLINICAL SYNDROMES

In addition to infectious mononucleosis, EBV is also associated with neoplasia and lymphoproliferative disorders, which are seen most frequently in patients with defects in cellular immunity but are not restricted to such patients.

POST-TRANSPLANT LYMPHOPROLIFERATIVE DISORDER

EBV-transformed B-cell proliferation that is insufficiently contained by T-cell activity is initially similar to what is seen in acute infectious mononucleosis, but then progresses to a lymphoproliferative disorder.

EPIDEMIOLOGY

This syndrome most frequently occurs in the setting of solid-organ transplantation, especially when patients acquire a primary EBV infection and/or have been immunosuppressed with agents directed specifically at T lymphocytes. This lymphoproliferative disorder also can be seen in other conditions with similar levels and durations of immunodeficiency, such as advanced HIV-1 infection (Chapter 359).

Post-transplant lymphoproliferative disorder (often simply called PTLD)[5,6] is often but not invariably EBV driven. EBV-associated post-transplant lymphoproliferative disorder is seen earlier in the post-transplant course than non–EBV-associated cases and is seen more often when the donor is EBV seropositive and the recipient is seronegative. Among recipients of solid-organ transplants, post-transplant lymphoproliferative disorder is more common in the setting of more severe immunosuppression (Chapter 38), including multiple-organ transplants, but it can occur in any recipient (Chapter 38). Among stem cell transplant recipients (Chapter 163), the most important risk factor is the level of T-cell depletion of the donor cells. However, other risk factors include the use of stem cells from HLA-mismatched donors, intensive immunosuppression, and primary immunodeficiency.

PATHOBIOLOGY

The majority of PTLD lesions are associated with EBV infection and consist of EBV-induced monoclonal or polyclonal B-cell proliferations. Monoclonal T-cell proliferation occurs less often. Among solid-organ transplant recipients, the lesions are most often of host cell origin. In contrast, PTLD lesions occurring among stem cell allograft recipients are typically of donor cell origin. Histopathologically, the four major categories of PTLD are non-destructive lesions, polymorphic PTLDs, monomorphic PTLDs, and classic Hodgkin lymphoma PTLD. Except for polymorphic PTLDs, these categories are further subcategorized. For example, Burkitt lymphoma lesions represent a subcategorization of B-cell monomorphic PTLDs, whereas plasmacytic hyperplasia, infectious mononucleosis-like lesions, and florid follicular hyperplasia represent subcategories of nondestructive PTLDs.

CLINICAL MANIFESTATIONS

Patients with post-transplant lymphoproliferative disorder can present with early-onset (within 2 years) or later onset disease (greater than 2 years after transplantation). Constitutional symptoms are typically common with the later onset syndrome. There is a predilection for the reticuloendothelial system and the transplanted organs (except heart) to be involved. Clinical manifestations may include fever, weight loss, lymphadenopathy, hepatosplenomegaly, subcutaneous nodules, tonsillar enlargement, tonsillar inflammation, signs of bowel perforation, mucocutaneous ulceration, intracranial lesions, and focal neurologic signs depending on location of lesions.[7,8]

DIAGNOSIS

Elevated levels of EBV DNA in whole blood, peripheral blood lymphocytes, or plasma are associated with an increased likelihood of post-transplant lymphoproliferative disorder, but the absence of elevated levels does not exclude the diagnosis. The diagnosis of post-transplant lymphoproliferative disorder typically requires histopathologic confirmation. Besides confirming the diagnosis, tissue examination enables the further characterization of the lesion, in terms of its immunophenotype, clonality, CD20 positivity, EBV status, and the presence or absence of tumor genetic/cytogenetic markers.

TREATMENT AND PREVENTION

Although many centers use universal CMV-like antiviral (ganciclovir or valganciclovir) prophylaxis strategies (Chapter 347) for high-risk EBV-mismatched transplant recipients, this strategy remains controversial. Antiviral agents are less useful once post-transplant lymphoproliferative disorder develops. In response to elevated EBV loads prior to the onset of post-transplant lymphoproliferative disorder, the anti-CD20 agent rituximab under expert oversight appears to be beneficial for stem cell transplant recipients. For solid-organ transplant patients, the most widely accepted preemptive strategy is to reduce immunosuppression whenever feasible.

Successful management of post-transplant lymphoproliferative disorder depends on the extent to which the immunosuppression can be reduced or even reversed before and after the development of frank post-transplant lymphoproliferative disorder. In addition to reduced immunosuppression, therapy with rituximab, with or without chemotherapy, is the treatment of choice for the majority of patients (Chapter 171). Surgical excision (e.g., adenoids or bowel), radiation, and adoptive T-cell therapies are also used, depending on the histopathology of the lesions.

BURKITT LYMPHOMA

EBV is the cause of Burkitt lymphoma. The tumor is composed of small, non-cleaved B cells and, unless aggressively treated, is rapidly fatal. This aggressive B-cell lymphoma with a predilection for the head and neck[9] is endemic in equatorial Africa and is geographically linked to *Plasmodium falciparum* malaria, which is believed to play role in the genesis of this lymphoma. EBV DNA is readily demonstrable in tumor biopsy specimens, and high titers of antibodies to EBV structural antigens are found in plasma. Sporadic cases of abdominal B-cell lymphomas with a histologic appearance compatible with Burkitt lymphoma are also observed but are associated with EBV only about 25% of the time.

The tumor is likewise seen in patients with HIV infection (Chapter 359). Although the risk for HIV-associated Burkitt lymphoma increases with advancing immunodeficiency, it may be seen in patients with relatively preserved CD4 cell counts. Antiretroviral therapy reduces but does not eliminate the risk for Burkitt lymphoma in HIV-1–infected persons. Despite the high-grade clinical behavior of the tumor, it should be vigorously treated because it is usually quite responsive to combination chemotherapy with or without radiation therapy (Chapter 171).[10]

HODGKIN LYMPHOMA

EBV is also associated with a subset of Hodgkin lymphomas (Chapter 172),[11] especially the lymphocyte-depleted or mixed-cellularity histologic subtypes. EBV DNA and proteins are detected in the Reed-Sternberg cells that are characteristic of Hodgkin lymphoma. Therapy for EBV-associated Hodgkin lymphoma is directed at the tumor. The specific approach used is based on the histology and extent of disease (Chapter 172) and is not determined in a given patient by its relationship to EBV.

CENTRAL NERVOUS SYSTEM LYMPHOMA

EBV is also associated with central nervous system (CNS) lymphoma (Chapter 171).[12] This tumor is seen in the post-transplant setting but is also now the most frequent CNS neoplasm in HIV-infected individuals. The major differential diagnostic challenge is with *T. gondii* infection (Chapter 320). Although a tissue-based diagnosis is definitive, noninvasive neurodiagnostic approaches coupled with the demonstration of EBV DNA in cerebrospinal fluid by polymerase chain reaction can strongly support the diagnosis of lymphoma over that of *T. gondii* infection. In addition to chemotherapy, radiation therapy has been used, but its effects are generally palliative.

NASOPHARYNGEAL CARCINOMA

EBV has also been associated with certain cases of nasopharyngeal carcinoma (Chapter 176).[13] This tumor is rare in Western countries, but it is much more frequent in southern China and in the Inuit population of Alaska. EBV-associated cases are generally less histologically differentiated than sporadic forms of nasopharyngeal carcinoma. EBV DNA is demonstrable in tumor tissue, and high titers of IgA and IgG antibodies to the EBV capsid antigens are found in plasma. The prognosis for this tumor is poor, although it is often treated with radiation therapy (Chapter 176).

HISTIOCYTOSES AND LYMPHOMATOID GRANULOMATOSIS

EBV DNA may be found in moderate to slowly progressive destructive midline facial angiocentric tumors of T- and NK-cell phenotypes. This neoplasm presents clinically as a syndrome that was previously known as lethal midline granuloma (Chapter 155). EBV also plays a key role in the pathogenesis of an angiocentric EBV-associated B-cell tumor, which presents clinically as lymphomatoid granulomatosis and hemophagocytic lymphohistiocytosis (Chapter 155).[14]

Lymphomatoid granulomatosis is a very rare lymphoproliferative disease that likely results from defective immune surveillance in the absence of a primary immunodeficiency.[15] It universally affects the lungs but also commonly involves skin, liver, kidneys, and the central nervous system.

TREATMENT

Treatment under expert guidance attempts to augment the immune response to EBV and may include interferon α2b for low-grade disease and immunochemotherapy (e.g., etoposide, corticosteroids, vincristine, cyclophosphamide, doxorubicin, and rituximab) for high-grade disease. Stem cell transplantation may be considered for primary refractory disease or multiple relapses. For hemophagocytic lymphohistiocytosis, which is a life-threatening hyperinflammatory syndrome, treatment must be guided by specialty experts. Etoposide and dexamethasone can induce temporary remission, but nivolumab may be preferred for relapsed or refractory disease because it can restore a defective anti-EBV response and may avoid the need for allogeneic stem cell transplants.[16]

OTHER EBV-ASSOCIATED NEOPLASMS

EBV is recognized as a cause of gastric carcinoma (Chapter 178),[17] in which it is reported to be responsible for 2 to 20% of cases. EBV also collaborates with another human gamma-herpesvirus, human herpesvirus type 8, to cause primary effusion lymphoma in HIV-infected patients (Chapter 171). These aggressive tumors present in body cavities such as the pleural, peritoneal, and pericardial spaces. EBV is also implicated in a variety of other tumors, including leiomyosarcomas and smooth muscle tumors (Chapter 187), in immunocompromised hosts.

ORAL HAIRY LEUKOPLAKIA

Oral hairy leukoplakia is characterized by a corrugated or plaquelike lesion that extends around the lateral aspects of the tongue (Fig. 393-5). Oral hairy leukoplakia is most often observed in individuals with chronic forms of cellular immunodeficiency, especially patients who have HIV infection and CD4 cell counts less than 200/μL. It is most often clinically confused with mucocutaneous candidiasis (Chapter 310) but can be differentiated because its distribution is restricted to the lateral surface of the tongue. Unlike thrush, it does not involve the buccal mucosa, palate, or pharynx and is not readily removed by superficial scraping. Biopsies demonstrate a characteristic histopathologic pattern, as well as the presence of EBV antigens and DNA within squamous epithelial cells. Although the lesions maybe cosmetically troublesome, they are not generally painful. In HIV-associated oral hairy leukoplakia, the lesions resolve with successful antiretroviral chemotherapy (Chapter 357).

CHRONIC ACTIVE EBV INFECTION

Infrequently, patients with no apparent defect in cellular immunity have been described to have chronic EBV infection, which has been associated with persistent or intermittent clinically significant infection of more than 6 months' duration. In the United States, patients most often have disease involving B or T cells, whereas the disease usually involves T or NK cells in Asia. Patients may present with fever, lymphadenopathy, splenomegaly, hepatitis, or pancytopenia. Progressive immunodeficiency may develop, and untreated patients succumb to opportunistic infections, hemophagocytosis, multiorgan failure, or EBV-positive lymphomas. Hematopoietic stem cell transplantation is the only proven therapy.

Patients with this severe chronic infection should not be confused with individuals who have chronic fatigue syndrome or fibromyalgia rheumatica (Chapter 253). This nonspecific clinical syndrome, which is seen most frequently in young and middle-aged women, is characterized by malaise and difficulty concentrating without objective physical findings. There is no evidence that EBV plays a role in this condition.

349 ENTEROVIRUSES

JOSÉ R. ROMERO

DEFINITION

The enteroviruses belong to the genus *Enterovirus* in the family Picornaviridae. With the advent of molecular virology, the more than 110 recognized strains are classified on the basis of phylogenetic analysis of the nucleic acid sequence of VP1, which is the major enteroviral capsid protein (Table 349-1).

The Pathogens

Enteroviruses are small (30 nm in diameter), nonenveloped, icosahedral-shaped viruses. The viral capsid is composed of four viral proteins (VP1 to VP4). The enteroviruses possess an approximately 7.4-kilobase positive-sense single-stranded RNA genome. The 5′ end of the genome is covalently linked to a small protein, VPg. The genome is organized into a long (about 740 nucleotides) 5′ nontranslated region that precedes a single continuous open reading frame measuring about 6.63 kilobases. The open reading frame, which is followed by a short 3′ nontranslated region and a terminal polyadenylate tail, yields a single large polyprotein that is post-translationally modified to produce four capsid proteins, seven nonstructural proteins, and several functional protein intermediates. The 5′ and 3′ nontranslated regions participate in replication of the viral genome. The 5′ nontranslated region of the enterovirus is essential for translation and contains determinants of neurovirulence in the polioviruses.

ABSTRACT

The enteroviruses belong to the genus *Enterovirus* in the family Picornaviridae. Of the 15 species in the genus, four (Enterovirus A–D) are pathogenic for humans and contain more than 110 recognized strains based on phylogenetic analysis of the nucleic acid sequence of the capsid protein VP1. Enteroviruses are small, are nonenveloped, and possess an RNA genome. Worldwide, an estimated 1 billion infections occur annually, and humans are the only known reservoir. In the United States enteroviruses cause approximately 10 to 15 million symptomatic cases annually. Infections are seasonal, with the majority occurring during the summer and early autumn in temperate climates. More than 80% of infections are in individuals younger than 20 years of age, with the highest incidence in young children. The enteroviruses can affect nearly every organ system. They cause a wide spectrum of febrile exanthems and enanthems, including hand-foot-and-mouth disease and herpangina. Although poliomyelitis is on the threshold of elimination owing to effective vaccination programs worldwide, enteroviruses remain the most common cause of central nervous system infections (meningitis, encephalitis, flaccid paralysis) in the United States. Enteroviruses are responsible for approximately a third of the cases of acute viral myocarditis. Individuals with congenital or acquired B-cell immunodeficiencies may develop prolonged or chronic infections. Nucleic acid amplification is the method of choice for diagnosing enteroviruses. No specific therapy exists for the treatment of enteroviral infections, but vaccines are effective for the prevention of poliovirus and enterovirus A71.

enterovirus A71

EPIDEMIOLOGY

Worldwide, an estimated 1 billion or more enteroviral infections occur annually. In the United States about 30 to 50 million annual infections result in approximately 10 to 15 million symptomatic cases, with enterovirus D68, echovirus 30, coxsackievirus A6, echovirus 18, coxsackievirus B3, echovirus 9, and enterovirus 11 accounting for approximately 80% of enteroviral infections.[1]

Humans are the only known reservoir for enteroviruses. Enteroviral infections are seasonal, and the majority of infections occur during the summer and early autumn in temperate regions. For example, more than 80% of infections occur in the United States from June through October. However, winter outbreaks highlight their panseasonal occurrence. In tropical and subtropical regions, infections continue year-round, with an increased incidence during the rainy season.

Globally, the dominant circulating enterovirus serotypes may vary annually by geographic region. In the United States 7 serotypes accounted for nearly 80% of all isolates reported (Table 349-2).

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic has impacted enteroviral surveillance. Globally, reports of acute flaccid paralysis cases have decreased by 33%.[2] This decrease is most likely due to multiple factors including a reluctance to seek medical care as result of fear of contagion and decreased active surveillance during this period.

More than 80% of infections occur in individuals younger than age 20 years, with the highest incidence in infants and children ages 4 years and younger. Nearly 45% of all infections occur in infants younger than 1 year. Among household members of infected children, clinical or serologic evidence of secondary infection can be seen in more than 50% of susceptible individuals. A male preponderance is noted in persons younger than age 20 years (male-to-female ratio of 1.4 : 1) but not in older individuals.

Localized enteroviral outbreaks have been reported in neonatal units, nurseries, daycare centers, schools, camps, sports teams, and military facilities. Community-wide outbreaks are common. Extensive regional outbreaks of EV-A71 have occurred in the Asia-Pacific region. Occasional pandemics, such as acute hemorrhagic conjunctivitis caused by EV-D70 and CV-A24, also have occurred.

Effective antipolio immunization programs have eradicated 2 of the 3 wild-type poliovirus serotypes (serotypes 2 and 3) worldwide. Cases of serotype 1 are now restricted to only Afghanistan and Pakistan, where it remains endemic.[3]

The use of live attenuated poliovirus vaccines led to the problem of vaccine-derived polioviruses as a result of the excretion of neurorevertant vaccine (Sabin) strains from individuals who have primary humoral immunodeficiencies, but not secondary humoral or other immunodeficiencies, or as a result of natural recombination between Sabin strains and members of the Enterovirus C species.[4] Vaccine-derived polioviruses that can circulate in the environment with evidence of person-to-person transmission have been termed *circulating vaccine-derived polioviruses*. A third group, designated ambiguous vaccine-derived polioviruses, are clinical isolates from individuals without known immunodeficiency or sewage isolates whose ultimate source is unknown. Similar to wild-type poliovirus, circulating vaccine-derived polioviruses can cause acute flaccid paralysis in unimmunized or incompletely immunized individuals and have caused multiple outbreaks worldwide.

To reduce the risk for poliomyelitis owing to vaccine-derived polioviruses, all use of trivalent oral polio vaccine ceased globally in April 2016 and was replaced with a bivalent oral vaccine that contains only types 1 and 3 attenuated polioviruses. A monovalent type 2 oral polio vaccine is available for immunization in response to outbreaks. In an attempt to decrease the number of circulating vaccine-derived poliovirus outbreaks due to type 2 vaccine, a novel type 2 oral polio vaccine with a substantially lower risk of neurovirulence reversion has been approved for use by the World Health Organization.

TABLE 349-2 THE 13 MOST COMMON ENTEROVIRUS SEROTYPES REPORTED BY NATIONAL ENTEROVIRAL SURVEILLANCE SYSTEM LABORATORIES TO THE CDC, 2009–2013

ENTEROVIRUS SEROTYPE	PERCENTAGE
Enterovirus D68	55.9
Echovirus 30	5.8
Coxsackievirus A6	5.5
Echovirus 18	4.2
Coxsackievirus B3	4.0
Echovirus 9	2.4
Echovirus 11	2.3
Parechovirus A3	2.3
Coxsackievirus B4	2.0

From Centers for Disease Control and Prevention (CDC). Enterovirus and parechovirus surveillance—United States, 20014-2016. *MMWR Morb Mortal Wkly Rep*. 2018;67:515-518.

PATHOBIOLOGY

The polioviruses and the majority of the nonpolio enteroviruses are transmitted through a fecal-oral route. Notable exceptions include CV-A21 and EV-D68, which are spread by the respiratory route, and EV-D70, which may spread by contaminated fomites or ocular and respiratory secretions. Evidence also supports transplacental transmission of the enteroviruses.

Ingestion of the enteroviruses results in infection of cells of the pharynx and, because the virus is acid resistant, the lower gastrointestinal tract. Initial viral replication, which is thought to occur in the mucosal tissues of the nasopharynx and intestinal tract (i.e., tonsils and Peyer patches), leads to seeding of the deep cervical and mesenteric lymph nodes. Further replication at these sites results in a minor viremia with seeding of multiple organs, including the liver, lungs, heart, and central nervous system (CNS). Viral replication at these sites causes many of the clinical manifestations of infection and is followed by a major viremia that may infect the CNS if it was spared during the initial viremia. The virus is cleared by type-specific neutralizing antibodies directed at the capsid proteins by day 7 to 10 after infection. Immunoglobulin (Ig)A antibodies appear in the respiratory and gastrointestinal tracts 2 to 4 weeks after infection.

The host humoral immune response is pivotal in the prevention and eradication of enteroviral infections. Congenital or acquired B-cell immunodeficiencies may result in chronic or prolonged infection. Experimental evidence suggests that the interferons are important in limiting the spread of poliovirus once infection has occurred. Natural killer cells and gamma or delta T cells may play roles in regulating the host T-cell response.

Histopathologic findings in patients who died of poliomyelitis reveal neuronal necrosis in association with mononuclear and polymorphonuclear infiltrates that are initially perivascular in distribution but are later found diffusely within the gray matter of the anterior horns of the spinal cord, the reticular formation of the hindbrain, the vestibular nuclei, and the roof nuclei of the cerebellum. In nonpolio enterovirus CNS infections in immunocompetent hosts, findings include edema of the meninges and cerebral parenchyma, with microscopic perivascular lymphocytic infiltration, increased numbers of oligodendrocytes, and focal areas of necrosis and hemorrhage. In cases of enteroviral myocarditis (Chapter 47), a mononuclear cell inflammation is associated with widespread myocardial necrosis followed by fibrosis, which may be focal but results in myocardial damage.

CLINICAL MANIFESTATIONS

The incubation period for enterovirus infections is generally 3 to 6 days, with a range of 2 days to 2 weeks. Depending on serotype and the age of the patient, as many as 90% of infected individuals may have subclinical infections.[5] The enteroviruses are responsible for a wide array of clinical syndromes that affect nearly every organ system, and no enteroviral serotype is uniquely associated with a single disease or clinical syndrome (Table 349-3).

The most frequent enteroviral syndrome, seen in about 50 to 80% of cases, is nonspecific febrile illness, which occurs most commonly in infants, toddlers, and young children. The onset of illness is abrupt, with fever, poor appetite, lethargy, irritability, emesis, diarrhea,[6] and upper respiratory tract symptoms. Physical findings are minimal and consist of mild pharyngeal and conjunctival injection and lymphadenopathy. Exanthems may be present in about 25% of cases.

DIAGNOSIS

Nucleic acid amplification techniques (e.g., reverse transcription–polymerase chain reaction [RT-PCR] and nucleic acid–based sequence amplification) are

TABLE 349-3 CLINICAL MANIFESTATIONS OF NONPOLIO ENTEROVIRUS INFECTIONS*

CLINICAL SYNDROME	GROUP A COXSACKIEVIRUSES†	GROUP B COXSACKIEVIRUSES	ECHOVIRUSES	ENTEROVIRUSES

Lower respiratory tract infections (bronchiolitis, pneumonia)	7, 9, 16	1, 2, 3, 4, 5	4, 8, 9, 11, 12, 14, 19, 20, 21, 25, 30	D68, A71, C104
Acute hemorrhagic conjunctivitis‡	24			D70
Generalized disease of the newborn	3, 9, 16	1, 2, 3, 4, 5	3, 4, 6, 7, 9, 11, 12, 14, 17, 18, 19, 20, 21, 30	

*A great many enterovirus serotypes have been implicated in most of these syndromes, at least in sporadic cases. The serotypes listed are those that have been clearly or frequently implicated. Serotypes with a strong association are underlined.

†Because detection of many of the group A coxsackieviruses originally required suckling mouse inoculation, they are likely to be underreported as causes of illness.

‡Conjunctivitis without hemorrhage is frequently seen in association with other manifestations in patients infected with many group A and group B coxsackieviruses and echoviruses, especially coxsackieviruses A9, A16, and B1 to B5 and echoviruses 2, 7, 9, 11, 16, and 30.

From Modlin JR. Enterovirus. *Cecil Textbook of Medicine*. 23rd ed. Philadelphia: WB Saunders; 2008, with minor changes.

the preferred methods for detection and identification of all enteroviruses. RT-PCR can detect enteroviruses in cerebrospinal fluid (CSF), blood, tissue, stool, and other body fluids within hours, and their rapid results can shorten hospitalizations, decrease the use of antibiotics, and reduce health care costs.

Serologic testing is of limited use, although a four-fold change in antibody titer to a specific serotype of enterovirus in paired acute and convalescent sera can help establish the diagnosis in patients who are no longer actively infected. Cell culture is not recommended.

TREATMENT AND PROGNOSIS

Nonspecific febrile enteroviral infections generally resolve in less than 5 days without sequelae. Because of concern for possible occult bacterial infection, however, significant numbers of young infants and children are hospitalized for evaluation and empirical therapy. After infection, virus may be shed into the nasopharynx for 2 to 6 weeks and in feces for several months.

SPECIFIC CLINICAL SYNDROMES

Central Nervous System Infections

ACUTE FLACCID PARALYSIS/MYELITIS

CLINICAL MANIFESTATIONS AND DIAGNOSIS

During poliovirus epidemics, 90 to 95% of infections are subclinical. In another 4 to 8% of patients, infection results in fever, fatigue, headache, anorexia, myalgia, and sore throat, which resolve in 2 to 3 days. Paralytic polio develops in less than 1% of infected individuals.

Acute flaccid myelitis can be seen with other enteroviruses (especially CV-A7, EV-A71), and EV-D68, with sporadic cases or clusters reported worldwide.[7,8] Cases of EV-A71 associated paresis have tended to occur in the Asia-Pacific region, although cases also have been reported from the United States and Europe. Rhombencephalitis may result in autonomic dysfunction, myoclonus, and ataxia. In United States, EV-D68 is believed to be the major cause of the biennial outbreaks of acute flaccid myelitis that have occurred since 2014, with the exception of 2020, the initial year of the SARS-CoV-2 pandemic.[9] Acute flaccid myelitis predominantly affects children, the majority of whom have a prodrome of fever and respiratory symptoms. The onset of neurologic symptoms occurs within 10 days following the initiation of the prodromal phase. Early neurologic findings may include headache, nuchal rigidity, and meningismus. Weakness is preceded by pain in the involved muscles. The weakness and paralysis are flaccid in nature and asymmetric. Deep tendon reflexes in the involved extremities are decreased or absent. Upper extremities and proximal muscle groups are more frequently involved, but respiratory muscles, diaphragm, trunk, and neck can also be affected. The brainstem motor nuclei of the cranial nerves may be involved. Respiratory failure secondary to involvement of the muscles of respiration or brain stem may occur. Dysfunction of the bowel and bladder are common. Sensory pathways remain intact as does mental status.

CSF may reveal a normal cell count or a mild lymphocytic pleocytosis (<100 cells/μL) in association with mildly increased protein and normal glucose concentrations. Magnetic resonance imaging of the spinal cord demonstrates T2-weighted hyperintensity of the gray matter (anterior horn regions) that is longitudinally expansive. T2 hyperintensity can also be seen in the brainstem.

TREATMENT AND PROGNOSIS

No specific therapy exists. Efforts should focus on monitoring for the development of respiratory failure or airway compromise as well as control of pain associated with muscle spasms.

The mortality rate associated with spinal poliomyelitis is about 5%. The mortality rates for enteroviruses associated with nonpolio enteroviral acute flaccid paralysis are not known. Before modern methods of respiratory and cardiovascular support, mortality rates higher than 50% were common in patients with bulbar or medullary poliomyelitis. The ultimate outcome of the paralysis is highly variable and can range from complete resolution to lifelong persistence. The greatest gains in recovery of strength occur during the first 6 months of convalescence. Paralytic limbs become atrophic, thereby leading to skeletal deformities. In a Colorado outbreak of EV-D68, about 75% of patients had limited or no improvement of their flaccid paralysis at 30 days, and the other 25% had only partial recovery by that time. By comparison, 93% of children with EV-A71 neurologic diseases in Colorado completely recovered within 2 months.[10]

A syndrome of postpoliomyelitis muscle atrophy, which may be seen in 25 to 85% of individuals two to three decades after recovery from paralytic disease, is characterized by the gradual development of weakness, pain, and atrophy. Possible mechanisms include aging and neuronal dropout in compromised neuromuscular connections or, less likely, reactivation/ongoing poliovirus infection.

MENINGITIS

Worldwide, the enteroviruses, especially those within the Enterovirus B species, are the dominant cause of viral meningitis (Chapter 381) in all ages. About 50% of all cases of meningitis and encephalitis in the United States are documented to be enteroviral infections.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical picture varies with age. In older infants and children, an abrupt onset of fever is the most frequent initial symptom. The fever may persist for 1 to 5 days and may exhibit a biphasic pattern. Irritability or lethargy is common. Other nonspecific symptoms include poor feeding, vomiting, diarrhea, and rash. Headache is present in nearly all children old enough to report it. Rash, malaise, sore throat, abdominal pain, and myalgia are common,[11] and photophobia may be reported. Seizures occur in less than 5% of cases. Examination may reveal a full fontanelle. Signs of meningeal irritation (i.e., nuchal rigidity, Brudzinski and Kernig signs) occur in less than 10% of infants younger than 3 months and increase with age.

In adolescents and adults, headache is nearly always present [12] and severe enough to require narcotic analgesics for control. Some patients report temporary relief of headache after lumbar puncture. Fever is not universal, but photophobia, signs of meningeal irritation, nausea, emesis, and neck stiffness occur in more than two thirds of patients. Myalgia is reported in 20 to 90% of patients. Less frequent findings include rash and abdominal pain.

CSF analysis generally reveals a mild to moderate lymphocytic pleocytosis (<500 cells/μL). Some patients, however, may have lymphocyte counts higher than 1000 or have neutrophilic pleocytosis early in the course of illness and then progress to a predominance of lymphocytes hours to days later. In a small percentage of patients, particularly infants, no pleocytosis is present even though enterovirus can be detected. The protein concentration may be increased. Although the glucose concentration is generally normal, hypoglycorrhachia may occur, particularly in association with group B coxsackievirus meningitis. Neuroimaging in cases of meningitis is generally unrevealing. Nucleic acid amplification testing can detect enteroviruses in CSF. The serotypes most frequently identified from CSF specimens are from the enterovirus B species.

TREATMENT AND PROGNOSIS

Treatment is supportive, with control of fever and pain. Currently available antiviral agents are not helpful. Hospitalization may not be necessary in adolescents and adults who appear well if a bacterial cause can be confidently excluded. When bacterial infection cannot be confidently excluded in adults, hospitalization and initial empirical antimicrobial therapy are advisable (Chapter 381) while awaiting the results of bacterial cultures of blood and CSF. Intravenous fluids may be required to prevent dehydration. Control of headache pain may require narcotic analgesics. Uncommon complications in all ages include coma, increased intracranial pressure, and inappropriate secretion of antidiuretic hormone.

The overwhelming majority of patients recover fully. The duration of illness in infants and children is generally less than 1 week. In adults, full recovery may take up to 3 weeks.

ENCEPHALITIS

The enteroviruses are responsible for about 20% of identifiable causes of viral encephalitis (Chapter 383). In the single largest report of enterovirus-related encephalitis, about 75% of confirmed cases occurred in individuals younger than age 20 years, including about 40% of cases in patients younger than age 10 years.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The onset of neurologic findings may be abrupt or be preceded by fever, headache, malaise, myalgia, upper respiratory symptoms, rash, nausea, emesis, or diarrhea. Somnolence, lethargy, and altered consciousness are common. Patients may exhibit irritability, changes in personality, or hallucinations. Generalized or focal seizures occur in up to 30% of patients, and a minority of patients may progress to coma. Neck stiffness and ataxia are frequent physical findings. Focal neurologic findings such as hemiplegia, hemichorea, and paresthesias are reported in nearly 30% of patients. The focal nature of the seizures and abnormal neurologic findings may be reminiscent of herpes simplex virus encephalitis (Chapter 345).

Among enteroviral encephalitides, EV-A71 is uniquely associated with severe brain stem encephalitis (rhombencephalitis), primarily in children. The initial manifestation may be a prodrome of either hand-foot-and-mouth disease or herpangina, which is followed by myoclonus that may be associated with ataxia, tremors, or cranial nerve abnormalities and a rapid onset of neurogenic pulmonary edema, shock, coma, and apnea.

Evaluation of CSF may reveal mild to moderate lymphocytic pleocytosis (<500 cells/μL), but the CSF white cell count may be normal. The protein concentration may be increased and may be the sole abnormality. The glucose concentration is generally normal. Enteroviruses may frequently be detectable by nucleic acid amplification testing of CSF.

TREATMENT AND PROGNOSIS

Management is supportive, with monitoring for the development of respiratory failure or airway compromise. Nearly 50% of patients require intensive care. In patients with focal neurologic findings, empirical acyclovir (10 to 15 mg/kg every 8 hours) is warranted until herpes simplex virus is excluded.

The median duration of hospitalization is less than 1 week, and mortality is below 10%. For severe EV-A71 rhombencephalitis, however, mortality may approach 70%. Long-term sequelae after rhombencephalitis include myoclonus, abducens nerve palsy, facial diplegia, ataxia, dysarthria, internuclear ophthalmoplegia, and central apnea.

MYOPERICARDITIS

Prior to the SARS-CoV-2 pandemic (Chapter 336), members of the Enterovirus B species, and especially the group B coxsackieviruses, were responsible for approximately a third of cases of acute myocarditis (Chapter 47), with the majority of cases occurring in young adults. Now that SARS-CoV-2 (Chapter 336) is a major cause of acute myocarditis, [13] the current contribution of enteroviruses to the burden of myocarditis remains to be determined.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

An upper respiratory tract infection may precede the onset of cardiac symptoms by 1 to 2 weeks. Fever may be present, and common initial symptoms include dyspnea, chest pain, and fatigue. Physical examination may reveal a gallop rhythm or a pericardial friction rub.

Cardiomegaly may be seen on the chest radiograph. Electrocardiographic findings vary and include low-voltage QRS complexes, ST segment depression, T wave inversion, pathologic Q waves, ventricular arrhythmias, and heart block. Echocardiographic findings include a decreased ejection fraction, ventricular dilation, and pericardial effusion. Blood troponin levels are frequently elevated. Cardiac magnetic resonance imaging may help localize areas of myocarditis. Myocardial biopsy is recommended in selected patients who have refractory heart failure or suspected giant cell myocarditis (Chapter 47); enterovirus can be detected by nucleic acid amplification tests.

TREATMENT AND PROGNOSIS

Supportive treatment includes bed rest and management of heart failure (Chapter 46), arrhythmias (Chapters 52 and 53), and pericarditis with or without pericardial effusion (Chapter 62). Immunosuppressive therapy is not generally recommended (Chapter 47). In approximately a third of patients with acute myocarditis, chronic dilated cardiomyopathy develops. In patients with pericarditis, recurrent pericardial effusions or chronic constrictive pericarditis may develop in the future.

EXANTHEMS AND ENANTHEMS

Enterovirus infections may result in a wide spectrum of febrile exanthems and enanthems, including macular, papular, maculopapular, morbilliform, rubelliform, vesicular, urticarial, papulopustular, and scarlatiniform types. Exanthems are more commonly observed in children ages 15 years or younger. Any serotype is capable of causing several different rashes. With the exception of CV-A16, no serotype is associated with a unique rash. Echovirus 9 and CV-A9 can cause petechial or purpuric rashes reminiscent of meningococcemia (Chapter 274).

HAND-FOOT-AND-MOUTH DISEASE AND HERPANGINA

Hand-foot-and-mouth disease is typically associated with Enterovirus A species, particularly CV-A16, CV-A6, and EV-A71.[14] Herpangina is also most commonly caused by the group A coxsackieviruses in the Enterovirus A species, but it has also been associated with group B coxsackieviruses, echoviruses, and enteroviruses from the Enterovirus B species.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hand-foot-and-mouth disease begins with low-grade fever, malaise, anorexia, and oral soreness. In 1 to 2 days, oral macules appear and then rapidly vesiculate and ulcerate. Oral lesions are typically distributed on the buccal mucosa and tongue, but they may also occur on the palate, uvula, anterior pillars, and gums. In approximately two thirds of patients, the enanthem is accompanied by an exanthem, with tender 3- to 7-mm vesicles on the dorsum of the hands and feet, frequently involving the palms and soles. Lesions may appear on the buttocks but tend not to be vesicular. Hand-foot-and-mouth disease associated with CV-A6 has a wider distribution of skin lesions that enlarge and vesiculate. Onychomadesis (loss of fingernails) can occur 1 to 2 months after the infection.

Herpangina begins with high fever, particularly in young patients. Additional findings include sore throat, mild cervical lymphadenopathy, sialorrhea, anorexia, dysphagia, abdominal pain, and emesis. Examination of the mouth and throat reveals 1- to 2-mm papulovesicular, grayish white lesions with an areola of erythema, primarily located on the anterior pillars of the tonsillar fauces. The soft palate, uvula, and tonsils may also be involved. Rarely, the posterior buccal surfaces and dorsal tip of the tongue may be involved. During a period of 2 to 3 days, the lesions increase to 3 to 4 mm in size. On average, five lesions are present.

TREATMENT AND PROGNOSIS

Hand-foot-and-mouth disease usually resolves in less than 1 week, and herpangina generally resolves in 10 days, both typically uneventfully and without the need for hospitalization or sequelae. Infants and young children may require hospitalization for administration of parenteral fluids. Disease associated with CV-A6 has a higher rate of hospitalization. Hand-foot-and-mouth disease due to EV-A71 may precede the development of life-threatening rhombencephalitis (see Encephalitis).

ACUTE HEMORRHAGIC CONJUNCTIVITIS

Acute hemorrhagic conjunctivitis (Chapter 391) is associated with EV-D70 and CV-A24. The illnesses caused by the two serotypes are indistinguishable from each other. However, acute hemorrhagic conjunctivitis caused by CV-A24 may be more commonly accompanied by upper respiratory and systemic symptoms and may be associated with less severe conjunctival hemorrhage. High secondary attack rates within households are common. Other enteroviruses can cause acute conjunctivitis or keratoconjunctivitis but generally without hemorrhagic manifestations.

CLINICAL MANIFESTATIONS

An incubation period of about 1 to 2 days precedes the rapid onset of palpebral swelling associated with lacrimation, photophobia, blurring of vision, and severe ocular pain. The hallmark subconjunctival hemorrhages vary in size from petechiae to large blotches. Although transient keratitis occurs frequently, it seldom results in subepithelial opacities. Preauricular adenopathy is common, but fever is not. An ocular mucopurulent discharge may occasionally be present.

TREATMENT AND PROGNOSIS

Management is supportive. The illness usually persists for 1 to 2 weeks, but complete recovery is generally the rule. A transient lumbar radiculomyelopathy and acute flaccid paralysis–like illness may develop in some patients.

RESPIRATORY TRACT SYNDROMES

The enteroviruses may cause upper and lower respiratory tract syndromes, alone or accompanying other syndromes. As determined by nucleic acid amplification testing, enteroviruses are responsible for up to 15% of upper respiratory tract syndromes. They also cause 18% of lower respiratory tract syndromes in hospitalized children and 25% of hospitalizations in patients with acute wheezing. EV-D68 and EV-C104 are being increasingly recognized as causes of respiratory tract disease. During the initial year of the SARS-CoV-2 pandemic, the incidence of enteroviral respiratory disease decreased,[15] most likely as a result of decreased transmission because of physical mitigation measures (e.g., use of face coverings, handwashing, social distancing) and school closures.[16]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The enterovirus "summer cold" (Chapter 329) consists of nasal congestion, rhinorrhea, and sneezing. Malaise and cough may be present. Fever and sore throat are typically absent or minimal.

Pharyngitis, tonsillitis, or pharyngotonsillitis begins abruptly with fever and sore throat. The nasopharynx, tonsils, uvula, and soft palate demonstrate erythema and inflammation. Petechiae may be present, and cervical lymphadenitis is common. Other syndromes associated with the enteroviruses include bronchitis (Chapter 84) and bronchiolitis.

Enteroviral pneumonias begin gradually with coryza, anorexia, and low-grade fever. A nonproductive cough, tachypnea, retractions, nasal flaring, and wheezing may be present. In severe cases, cyanosis may develop. The chest radiograph may demonstrate perihilar infiltrates, patchy consolidation, air trapping, and atelectasis.

EV-D68 has become a cause of significant respiratory disease, primarily in young children and infants but also in adolescents and adults. An underlying pulmonary condition such as asthma or wheezing has been reported in up to 70 to 80% of cases. EV-D68–associated respiratory syndromes include pneumonia, bronchiolitis, asthmatic bronchitis, asthma exacerbation, and wheezing. Signs and symptoms include nasal congestion, rhinorrhea, cough, wheezing, dyspnea, tachycardia, and inter- and subcostal retractions. Acute flaccid paralysis is a rare complication. Interestingly, fever may be absent, but hypoxia is common. The chest radiograph may show infiltrates and atelectasis.

TREATMENT AND PROGNOSIS

Treatment is supportive and consists of control of fever and pain. In older children and adults, hospitalization is not usually required. Resolution occurs in 7 days or less. Hospitalization and admission to an intensive care unit may be required for respiratory support of EV-D68 infection. Death is uncommon but does occur.

MYOSITIS

PLEURODYNIA

The group B coxsackieviruses are the major cause of sporadic and epidemic pleurodynia, but the syndrome may also be caused by a limited number of echoviruses and group A coxsackieviruses within the Enterovirus A and B species.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The onset of illness is abrupt in approximately 75% of patients. In the remainder, the onset of pleuritic chest pain is preceded by a prodrome of headache, malaise, anorexia, and vague myalgia lasting up to 10 days. Pain may be referred to the lower ribs or the sternum, and it can radiate to the shoulders, neck, or scapula. Pain is exacerbated by deep breathing, coughing, sneezing, or movement. During paroxysms, patients tend to be tachypneic and to have shallow breathing. Additional findings can include abdominal pain, headache, cough, anorexia, nausea, vomiting, and diarrhea. Fever may be biphasic.

Physical examination does not generally reveal muscle tenderness, obvious myositis, or muscle swelling. A pleural friction rub may be present in 25% of patients. The chest radiograph is typically normal.

TREATMENT AND PROGNOSIS

Treatment is supportive, with an emphasis on nonsteroidal analgesics (e.g., ibuprofen, 200 to 400 mg per dose every 4 to 6 hours) or hydrocodone (5 to 10 mg four times per day) alone or in combination with acetaminophen to control pain. The symptoms may persist for 1 to 14 days (mean of 3.5 days) and resolve without sequelae, although recurrent symptoms may occur in 25% of patients.

INFLAMMATORY MYOSITIS

Multiple enteroviral serotypes are associated with focal or generalized myositis. In patients with B-cell immunodeficiencies, a dermatomyositis-like syndrome may develop.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Nonspecific findings include fever and chills. Involved muscles may be weak, tender, and edematous. Chemical evidence of myositis may be evidenced by elevated serum levels of creatine kinase, myoglobinemia, and myoglobinuria.

TREATMENT AND PROGNOSIS

Treatment is supportive. With the exception of patients with B-cell immunodeficiencies, recovery is complete and rapid.

ENTEROVIRUS INFECTIONS IN SPECIAL POPULATIONS

PATIENTS WITH B-CELL IMMUNODEFICIENCIES

Nonpolio enteroviruses and polioviruses may result in chronic or prolonged infections in patients with congenital or acquired B-cell immunodeficiencies (Chapter 231), such as patients who have inherent immunodeficiencies (e.g., X-linked agammaglobulinemia, hyper-IgM syndrome, severe combined immunodeficiency syndrome, or common variable immunodeficiency), or acquired immunodeficiencies (e.g., because of chemotherapy or immunomodulatory therapies, especially rituximab and obinutuzumab, or because of stem cell or solid organ transplantation).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Meningoencephalitis, pulmonary infections, and severe gastroenteritis can occur. The initial symptoms may consist of only persistent headaches and lethargy. As the disease progresses, additional neurologic findings develop and may include ataxia, loss of cognitive skills and memory, dementia, emotional lability, paresthesias, weakness, dysarthria, and seizures. Non-CNS manifestations include a dermatomyositis-like syndrome, edema, exanthems, and hepatitis. CSF demonstrates a persistently elevated protein concentration and pleocytosis. Enterovirus is detectable in CSF by RT-PCR.

TREATMENT AND PROGNOSIS

Children with humoral immunodeficiency (Chapter 231) should receive lifelong immunoglobulin replacement therapy in an attempt to prevent chronic infection. However, chronic meningoencephalitis develops in some patients and is usually ultimately fatal. Severe or fatal enteroviral infections have been reported in individuals receiving rituximab.

PREVENTION

Handwashing is the primary method for the prevention of enteroviral infections. Poliovirus infections are currently preventable through vaccination. Three EV-A71 China-licensed vaccines are at least 90% effective against EV-A71-related hand-foot-and-mouth disease[A1] and appear to be 100% effective against EVA-71-associated neurologic complications,[17] but they are not currently licenced in the U.S.

350 ROTAVIRUSES, NOROVIRUSES, AND OTHER GASTROINTESTINAL VIRUSES

MANUEL A. FRANCO AND HARRY B. GREENBERG

DEFINITION

Viruses are a principal cause of acute infectious gastroenteritis, a syndrome of vomiting, watery diarrhea, or both that begins abruptly in otherwise healthy persons. Two distinct viruses account for much of these cases. Before rotavirus vaccines were widely introduced over the last 15 years, rotaviruses accounted for over 400,000 deaths annually. Rotaviruses remain the most frequent cause of sporadic, severe gastroenteritis in young children worldwide, causing about 130,000 annual deaths in children younger than age 5 years,[1] mainly in developing countries that have not yet implemented widespread rotavirus vaccination. Noroviruses are the primary cause of epidemic infectious gastroenteritis in both infants and adults in developed countries. For example, outbreaks of gastroenteritis in closed settings, such as cruise ships and nursing homes, are a typical manifestation of epidemic norovirus infections. However, noroviruses are also an increasingly common cause of sporadic, mild to moderately severe gastroenteritis, especially in young children and adolescents,[2] and they are the leading cause of acute diarrhea in families with children in the Netherlands, even though it does not have a rotavirus vaccine program.[3] By comparison, in a birth cohort study from eight sites in South America, Africa, and Asia, rotavirus had the highest attributable burdens for sites without rotavirus vaccination.

The Pathogens

Noroviruses

Noroviruses, which are one of the five genera of the Caliciviridae family, are nonenveloped, icosahedral viruses with a relatively small, positive-sense, single-stranded RNA genome. The norovirus genus is further classified into 10 genogroups. Viruses in each genogroup are further divided into genotypes (more than 48 have been described), and a dual-typing nomenclature (genotype and P-type, depending on serology) has been proposed. Norwalk virus is a prototype genogroup I genotype 1 (GI.1) virus. The norovirus genome is approximately 7.7 kilobases in size and consists of three open reading frames, the first of which encodes the nonstructural proteins that are essential for virus replication. The second open reading frame encodes the major capsid protein, viral protein 1 (VP1). When VP1 is expressed as a recombinant protein, 180 molecules can autoassemble into virus-like particles (VLPs) that closely resemble authentic virions. These VLPs have proven to be critical to the study of noroviral epidemiology and immunity. Human noroviruses have only recently been reproducibly cultured in vitro in human enteroids,[4] so diagnosis generally depends on amplification of viral genes by polymerase chain reaction (PCR; see later) or use of VLPs as recombinant antigens for serologic analysis.

Rotavirus

Rotaviruses, which belong to the family Reoviridae, are large, icosahedral, nonenveloped viruses with a segmented, double-stranded RNA genome and a triple-layered protein coat. Rotaviruses are classified into nine species, A through I, on the basis of the presence of cross-reactive antigenic epitopes and their overall genetic relatedness. Species A rotaviruses are the most commonly encountered viral enteric pathogens of young humans and many other mammalian species. Species B viruses have been identified sporadically in outbreaks of adult diarrheal illness in China and more recently in studies of children with sporadic gastroenteritis, principally in India. Species C rotaviruses are primarily veterinary pathogens and are infrequently associated with diarrheal disease in humans and animals around the world when compared with species A. Species D through G rotaviruses have been isolated only from animals, primarily avian species. Rotaviruses are 100-nm particles that have three concentric layers of proteins: the core is composed of VP1, VP2, and VP3 and the segmented, double-stranded RNA genome; the intermediate layer is formed by VP6, the most abundant and antigenic viral protein; and the external layer is composed of VP7 and VP4. The genome, which is composed of 11 segments of double-stranded RNA that together are approximately 18 kilobases in length, encodes six structural and six nonstructural proteins. As is the case among virtually all other RNA viruses, the rotavirus RNA polymerase is error prone and, along with selective pressure such as the evolution of immunity, drives viral diversity. For rotaviruses, gene reassortment, which is the mixing of gene segments from different parental viruses in cells coinfected by two or more strains, and rearrangement of the viral genome also contributes to genetic diversity. Reassortment of gene segments between animal and human rotavirus strains also occurs in natural settings, especially in less developed countries. Recently an efficient and practical helper virus–free method was developed to recover recombinant rotaviruses, and this method will certainly lead to improved understanding of rotavirus biology as well as enhance the possibility of developing improved vaccines.[5]

Other Agents

Other viral agents that cause human acute infectious gastroenteritis that is difficult to distinguish from disease caused by rotaviruses and noroviruses include the sapovirus (like norovirus, a member of the Caliciviridae family), enteric adenoviruses (Chapter 333) belonging to types 40 and 41, and astroviruses (Table 350-1). The frequency of detection (by PCR assays) of these viruses in individuals with acute gastroenteritis depends on the setting, but

ENTEROVIRUS INFECTIONS IN SPECIAL POPULATIONS

PATIENTS WITH B-CELL IMMUNODEFICIENCIES

Nonpolio enteroviruses and polioviruses may result in chronic or prolonged infections in patients with congenital or acquired B-cell immunodeficiencies (Chapter 231), such as patients who have inherent immunodeficiencies (e.g., X-linked agammaglobulinemia, hyper-IgM syndrome, severe combined immunodeficiency syndrome, or common variable immunodeficiency), or acquired immunodeficiencies (e.g., because of chemotherapy or immunomodulatory therapies, especially rituximab and obinutuzumab, or because of stem cell or solid organ transplantation).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Meningoencephalitis, pulmonary infections, and severe gastroenteritis can occur. The initial symptoms may consist of only persistent headaches and lethargy. As the disease progresses, additional neurologic findings develop and may include ataxia, loss of cognitive skills and memory, dementia, emotional lability, paresthesias, weakness, dysarthria, and seizures. Non-CNS manifestations include a dermatomyositis-like syndrome, edema, exanthems, and hepatitis. CSF demonstrates a persistently elevated protein concentration and pleocytosis. Enterovirus is detectable in CSF by RT-PCR.

TREATMENT AND PROGNOSIS

Children with humoral immunodeficiency (Chapter 231) should receive lifelong immunoglobulin replacement therapy in an attempt to prevent chronic infection. However, chronic meningoencephalitis develops in some patients and is usually ultimately fatal. Severe or fatal enteroviral infections have been reported in individuals receiving rituximab.

PREVENTION

Handwashing is the primary method for the prevention of enteroviral infections. Poliovirus infections are currently preventable through vaccination. Three EV-A71 China-licensed vaccines are at least 90% effective against EV-A71-related hand-foot-and-mouth disease[A1] and appear to be 100% effective against EVA-71-associated neurologic complications,[17] but they are not currently licenced in the U.S.

350 ROTAVIRUSES, NOROVIRUSES, AND OTHER GASTROINTESTINAL VIRUSES

MANUEL A. FRANCO AND HARRY B. GREENBERG

DEFINITION

Viruses are a principal cause of acute infectious gastroenteritis, a syndrome of vomiting, watery diarrhea, or both that begins abruptly in otherwise healthy persons. Two distinct viruses account for much of these cases. Before rotavirus vaccines were widely introduced over the last 15 years, rotaviruses accounted for over 400,000 deaths annually. Rotaviruses remain the most frequent cause of sporadic, severe gastroenteritis in young children worldwide, causing about 130,000 annual deaths in children younger than age 5 years,[1] mainly in developing countries that have not yet implemented widespread rotavirus vaccination. Noroviruses are the primary cause of epidemic infectious gastroenteritis in both infants and adults in developed countries. For example, outbreaks of gastroenteritis in closed settings, such as cruise ships and nursing homes, are a typical manifestation of epidemic norovirus infections. However, noroviruses are also an increasingly common cause of sporadic, mild to moderately severe gastroenteritis, especially in young children and adolescents,[2] and they are the leading cause of acute diarrhea in families with children in the Netherlands, even though it does not have a rotavirus vaccine program.[3] By comparison, in a birth cohort study from eight sites in South America, Africa, and Asia, rotavirus had the highest attributable burdens for sites without rotavirus vaccination.

The Pathogens

Noroviruses

Noroviruses, which are one of the five genera of the Caliciviridae family, are nonenveloped, icosahedral viruses with a relatively small, positive-sense, single-stranded RNA genome. The norovirus genus is further classified into 10 genogroups. Viruses in each genogroup are further divided into genotypes (more than 48 have been described), and a dual-typing nomenclature (genotype and P-type, depending on serology) has been proposed. Norwalk virus is a prototype genogroup I genotype 1 (GI.1) virus. The norovirus genome is approximately 7.7 kilobases in size and consists of three open reading frames, the first of which encodes the nonstructural proteins that are essential for virus replication. The second open reading frame encodes the major capsid protein, viral protein 1 (VP1). When VP1 is expressed as a recombinant protein, 180 molecules can autoassemble into virus-like particles (VLPs) that closely resemble authentic virions. These VLPs have proven to be critical to the study of noroviral epidemiology and immunity. Human noroviruses have only recently been reproducibly cultured in vitro in human enteroids,[4] so diagnosis generally depends on amplification of viral genes by polymerase chain reaction (PCR; see later) or use of VLPs as recombinant antigens for serologic analysis.

Rotavirus

Rotaviruses, which belong to the family Reoviridae, are large, icosahedral, nonenveloped viruses with a segmented, double-stranded RNA genome and a triple-layered protein coat. Rotaviruses are classified into nine species, A through I, on the basis of the presence of cross-reactive antigenic epitopes and their overall genetic relatedness. Species A rotaviruses are the most commonly encountered viral enteric pathogens of young humans and many other mammalian species. Species B viruses have been identified sporadically in outbreaks of adult diarrheal illness in China and more recently in studies of children with sporadic gastroenteritis, principally in India. Species C rotaviruses are primarily veterinary pathogens and are infrequently associated with diarrheal disease in humans and animals around the world when compared with species A. Species D through G rotaviruses have been isolated only from animals, primarily avian species. Rotaviruses are 100-nm particles that have three concentric layers of proteins: the core is composed of VP1, VP2, and VP3 and the segmented, double-stranded RNA genome; the intermediate layer is formed by VP6, the most abundant and antigenic viral protein; and the external layer is composed of VP7 and VP4. The genome, which is composed of 11 segments of double-stranded RNA that together are approximately 18 kilobases in length, encodes six structural and six nonstructural proteins. As is the case among virtually all other RNA viruses, the rotavirus RNA polymerase is error prone and, along with selective pressure such as the evolution of immunity, drives viral diversity. For rotaviruses, gene reassortment, which is the mixing of gene segments from different parental viruses in cells coinfected by two or more strains, and rearrangement of the viral genome also contributes to genetic diversity. Reassortment of gene segments between animal and human rotavirus strains also occurs in natural settings, especially in less developed countries. Recently an efficient and practical helper virus–free method was developed to recover recombinant rotaviruses, and this method will certainly lead to improved understanding of rotavirus biology as well as enhance the possibility of developing improved vaccines.[5]

Other Agents

Other viral agents that cause human acute infectious gastroenteritis that is difficult to distinguish from disease caused by rotaviruses and noroviruses include the sapovirus (like norovirus, a member of the Caliciviridae family), enteric adenoviruses (Chapter 333) belonging to types 40 and 41, and astroviruses (Table 350-1). The frequency of detection (by PCR assays) of these viruses in individuals with acute gastroenteritis depends on the setting, but

ABSTRACT

Viruses are a principal cause of acute infectious gastroenteritis, which is a syndrome of vomiting, watery diarrhea, or both that begins abruptly in otherwise healthy persons. Two distinct viruses account for much of these cases. Even after rotavirus vaccines were widely introduced, rotaviruses remain the most frequent cause of sporadic, severe gastroenteritis in young children, causing about 130,000 annual deaths in children younger than 5 years of age worldwide, mainly in developing countries that have not yet implemented widespread vaccination. Noroviruses are the primary cause of epidemic infectious gastroenteritis in both infants and adults in developed countries. For example, outbreaks of gastroenteritis in closed settings, such as cruise ships, military units, or nursing homes, are typical of norovirus infections. However, noroviruses are also an increasingly common cause of sporadic, mild to moderate gastroenteritis, mostly in young children.

TABLE 350-1 EPIDEMIOLOGIC AND CLINICAL FEATURES OF NOROVIRUS AND ROTAVIRUS

	NOROVIRUS	ROTAVIRUS	ASTROVIRUS
Epidemics	Occurs year-round; outbreaks tend to peak in cold weather	Year-round in equatorial countries; winter peak in others	Winter epidemics in children and endemic year-round
Key driver of epidemics	Antigenic drift strains promoted by population-based immunologic pressure	Size of the susceptible birth cohort	Unknown
Transmission	Fecal-oral, water, and food-borne outbreaks	Fecal-oral	Fecal-oral
Severity of diarrhea in children	Mild to moderate but can be severe	Moderate to severe	Milder than rotavirus or norovirus
Reservoir	Humans are the only known reservoir of noroviruses that infect humans	Mostly humans, but rotaviruses from farm animals and pets (especially in developing countries) can rarely infect humans and very rarely spread	Humans are the only known reservoir of astroviruses that infect humans
Prevention	Viral protein 1–based vaccine in development	Several live attenuated vaccines available	No vaccine in development
Age predisposition	All ages	Primarily children <5 years; disease transmission in older family contacts is relatively low (<25%)	Generally children, but adults may also get disease

they are almost always detected much less frequently than either rotaviruses or noroviruses. Coronaviruses (Chapter 334), toroviruses, picobirnaviruses, picornavirus (Chapter 349), bocavirus, parechoviruses, and pestiviruses have also been isolated occasionally from persons with acute gastroenteritis, but their roles as causative agents of enteric disease remain unproven. Among patients with acute gastroenteritis, no etiologic agent is found in approximately 25 to 50% of cases.

EPIDEMIOLOGY

Norovirus

Over time, noroviruses appear to undergo antigenic drift in response to the acquisition of immunity in the general population. At present, gastroenteritis cases around the world are most frequently caused by strains of GII.4 norovirus, with new pandemic GII.4 strains generally appearing every 2 to 4 years.[6] However, pandemic strains seem to circulate for years prior to their worldwide distribution and do not develop from previous pandemic strains, thereby suggesting that these pandemics are driven by an interplay between pre-circulating antigenic diversity and temporal changes in host immunity. Outbreaks of gastroenteritis frequently take place in settings of close human contact, such as military establishments, cruise ships, nursing homes, and schools, especially in cold and dry weather (see Table 350-1). Viral spread is enhanced by the very high level of infectivity of noroviruses, as data suggest that 1 to 10 particles constitute an infectious dose.

Noroviruses of genotypes GII.4 and GII.3 also are currently responsible for about 12 to 20% of sporadic gastroenteritis in children younger than 5 years in both developed and developing countries.[7] In the United States, where rotavirus vaccination is now widespread, noroviruses have surpassed rotavirus as the principal cause of medically attended visits for gastroenteritis in children younger than 5 years. Among U.S. adults, norovirus may be second only to *Clostridioides difficile* (Chapter 271) as the cause of severe acute diarrhea,[8] with hospitalizations especially in individuals over age 80 years. Of note is that the prevalence of asymptomatic carriage of norovirus in adults is about 2 to 3%.[9]

Rotavirus

The incidence of rotaviral disease is similar in children in both developed and developing countries, suggesting that public hygiene measures such as access to clean water do not replace the need for an effective vaccine. In developed countries, before the implementation of highly effective vaccines, rotavirus was a major economic burden but rarely the cause of fatal disease; after the implementation of vaccines, the epidemiology of rotavirus disease changed substantially. For example in the United States, the annual winter rotavirus season was replaced by a biennial trend, with alternating low rates in even-numbered years and higher rates in odd-numbered years. Initial infections also are now being observed in older children and adolescents.[10]

In the temperate zones of the world, rotaviral illness occurs primarily during epidemic peaks in the cooler months of the year (see Table 350-1). This pattern is not seen, however, in countries within 10 degrees of the equator, where disease occurs in an endemic fashion year-round.

Antibodies against the two outer capsid proteins are the basis of serotypic classification of group A rotaviruses into G (glycoprotein, VP7) and P (protease-sensitive, VP4) serotypes. For technical reasons, P serotyping reagents are infrequently available, and classification is based on the P genotype (provided in brackets). Worldwide, most human infections are caused by just five types of group A rotavirus; P[8]G1 is by far the most common (approximately 53% of strains), followed by P[8]G3, P[4]G2, P[8]G9, and P[8]G4. In some developing areas such as India, Brazil, and Africa, P[6]G9, G5, and G8 rotaviruses, respectively, are also frequently encountered. Some human rotavirus strains may have arisen after reassortment with bovine or porcine rotavirus strains during mixed infection in susceptible children. A high prevalence of G12 viruses has recently been observed in several countries, suggesting that this serotype may be an emerging rotavirus strain. In sub-Saharan Africa and South Asia, where most of the gastroenteritis deaths in children younger than 5 years of age occur, rotavirus is the most common etiologic agent of severe diarrhea and causes an important nutritional burden in children.

PATHOBIOLOGY

Norovirus

Histo–blood group antigens (HBGAs) are the intestinal cell receptors for noroviruses and determine susceptibility to disease in a strain-specific manner. The HBGAs are complex carbohydrate oligosaccharides linked to proteins or lipids that are expressed on the mucosal epithelia of the digestive tract. All three major families of HBGA, the ABO, Lewis, and secretor families, are involved in binding noroviruses. The secretor status of an individual is controlled by the fucosyltransferase 2 (*FUT2*) gene. Secretor-negative individuals are specifically resistant to infection with the Norwalk virus (GI.1) and some GII viruses as well.

Although norovirus RNA has been detected in the bloodstream of up to 20% of patients with norovirus gastroenteritis, the site of primary viral replication is most probably in the gastrointestinal tract. Recently human noroviruses have been successfully cultivated and passaged in vitro in differentiated human stem-cell–derived intestinal epithelial cell organoid cultures. Consistent with the strong association of vomiting with norovirus disease, gastric emptying is delayed. Proximal jejunal biopsy specimens show blunting of the villi with crypt cell hyperplasia and cytoplasmic vacuolation, sometimes with an increase in epithelial cell apoptosis. A functional alteration of the epithelial barrier is likely to occur. Unknown at present is the effectiveness and persistence of long-term immunity in the context of natural infection, in which the infectious dose is generally quite low. However, both natural infection and vaccination induce both homotypic and heterotypic broadly neutralizing antibody responses, with the latter waning more rapidly.[11]

Rotavirus

For rotaviruses, HBGAs have also been recently proposed as receptors that determine susceptibility to disease in a strain-specific manner. Rotaviruses replicate in the villus tip cells of the small bowel, where the pathologic process includes shortening and atrophy of the villi, vacuolization of enterocytes, mononuclear infiltration in the lamina propria, and distention of the cisternae of the endoplasmic reticulum. However, the severity of clinical disease has not been directly related to the extent of intestinal pathology; rather, it is related to levels of viral RNA in stool.

During the initial phases of the disease, altered intestinal secretion, motility, and permeability contribute to the pathophysiologic mechanism of diarrhea.

Later during disease, malabsorption can occur. Rotaviral NSP4, encoded by rotavirus gene 10, is a viral enterotoxin that mediates, at least in part, the early secretory components of the diarrhea. It has also been postulated that viral infection increases intestinal motility by stimulating the enteric nervous system, possibly through NSP4. Whether and to what degree the enterotoxic effect of NSP4 is clinically relevant in children or other animal species remains to be fully determined. Rotavirus-infected cells release extracellular adenosine 5'-diphosphate (ADP) that activates P2Y1 purinergic receptors on neighboring bystander cells, which in turn induce intercellular calcium waves implicated in the release of serotonin and the development of diarrhea.[12] Infected individuals have a short period of viremia, but its clinical consequences are unclear other than correlating with the level of fever. However, most rotavirus-infected children have mild elevations in hepatic enzymes, thereby suggesting that low-level hepatitis may be a common occurrence.

Rotavirus serum IgA levels measured shortly after natural infection in children generally correlate with intestinal IgA levels and appear to also correlate with protection. One explanation for recurrent rotavirus (and norovirus) infections is that protection from reinfection is mediated by intestinal IgA, which is not long-lasting in humans. Another explanation is that protection is dependent on neutralizing antibodies to one or both highly variable outer-capsid rotaviral proteins. However, a widely available monovalent P[8]G1 vaccine induces significant protection against multiple strains with different serotypes, thereby supporting the conclusion that protective immunity to rotavirus infection is, in large part, heterotypic.

CLINICAL MANIFESTATIONS

Norovirus

The clinical manifestations of norovirus infection are variable and depend in part on the age of the individual infected. About one third of infections are asymptomatic, but symptoms include diarrhea, nausea, vomiting, abdominal cramps, fever, and malaise that generally persist for 1 to 3 days. In children younger than 11 years, disease typically begins with the sudden onset of vomiting and can last 4 to 6 days. Virus can be shed in low titers for up to 8 weeks from otherwise healthy individuals and for more than a year in patients with severe immunodeficiency syndromes. In neonates and premature infants, vomiting often is not a symptom, and infection has rarely been associated with necrotizing enterocolitis. To support the diagnosis of norovirus outbreaks, the following four criteria have been proposed: (1) vomiting in more than half of affected persons; (2) mean (or median) incubation period of 24 to 48 hours; (3) mean (or median) duration of illness of 12 to 60 hours; and (4) absence of bacterial pathogens in stool culture.

Rotavirus

Rotavirus diarrhea and dehydration tend to be more severe than illness caused by the other childhood enteric pathogens. Rotavirus diarrhea is watery, persists for approximately 5 days, is often preceded by the sudden onset of vomiting, and is frequently accompanied by fever and dehydration. The incubation period of rotavirus is estimated to be less than 48 hours. Viral excretion in feces persists for 10 days in most children and can persist for up to 57 days. By the age of 5 years in an unvaccinated setting, virtually all children have naturally acquired immunity to rotavirus, and very severe disease after this age is uncommon.

DIAGNOSIS

Norovirus

Reverse transcription–PCR (RT-PCR) is currently the procedure of choice to detect norovirus in clinical specimens, in food, and in water. Norovirus RNA is detected by RT-PCR in stool samples of up to 16% of healthy individuals, a finding that can substantially complicate the diagnosis of norovirus gastroenteritis and the determination of the true burden of disease. Although the relationship between disease symptoms and viral load has not been fully established, a relative threshold of positivity on a quantitative real-time RT-PCR is probably better for attributing disease to norovirus.

Rotavirus

Numerous enzyme-linked immunosorbent assays (ELISAs) for rotavirus are generally sensitive, specific, and easy to use under most conditions. PCR has the best sensitivity for detecting rotavirus and has permitted easy typing of viruses, but nearly 30% of healthy children younger than 1 year may be rotavirus positive, so it is difficult to associate gastroenteritis with the detection of viral RNA. Thus ELISA or quantitative RT-PCR (using a threshold level as for norovirus) is preferable for diagnosis of rotavirus gastroenteritis.

PREVENTION

Norovirus

The development of a norovirus vaccine for humans is likely to be a challenge owing to the antigenic heterogeneity among circulating strains, the propensity of noroviruses to undergo antigenic drift, waning immunity, and the lack of well-established correlates of protection. Nevertheless, an intramuscular bivalent norovirus GI.1/GII.4VLP-based vaccine candidate has recently shown promising efficacy in adults.[A1] Moreover a bivalent oral vaccine, which uses a nonreplicating adenoviral vector,[A2] and two parenteral tetravalent and bivalent vaccines are undergoing phase I clinical trials.

High percentage alcohol-based sanitizers (99.5% ethanol) and 10% povidone-iodine antiseptics are superior to other alcohol-based sanitizers at reducing norovirus contamination. Simple household antimicrobial hand soap and handwashing with tap water also decrease viral contamination.

Rotavirus

Two second-generation rotavirus vaccines are safe, effective, and cost-effective in developed and developing countries. The first (RV5, RotaTeq [Merck]) uses a modified pentavalent vaccine consisting of a mixture of a bovine rotavirus that expresses a variety of human rotavirus VP4 or VP7 encoding genes. The second (RV1, Rotarix [GlaxoSmithKline]) is a monovalent attenuated human rotavirus vaccine. More recently ROTAVAC[A3] (Bharat Biotech: an attenuated G9P[11] virus isolated from a human neonate) and RotaSiil (Serum Institute India: a pentavalent human-bovine reassortant vaccine) have also been licensed.

Although none of these vaccines fully prevent subsequent rotavirus infection or mild illness, all types effectively reduce the amount of severe illness, especially in developed countries. Protection rates in developed and middle-income countries for licensed rotavirus vaccines are similar, ranging from 70 to 80% against any rotavirus disease and 90 to 100% against severe gastroenteritis, but infections are still seen in children over 5 years of age.[13,14] In resource-poor settings, vaccination can safely and successfully be accomplished in neonates.[A4]

Licensed vaccines may slightly increase the risk of intussusception, although one large study in India did not find an increase.[15] Furthermore, the substantial benefits of vaccines[16] far outweigh this low-level risk. Even in the United States, where the burden of severe disease from rotavirus is lowest, the rotavirus vaccine has significantly reduced health care utilization and expenses for acute diarrhea in children.[17]

In the United States vaccination also has had an unexpected effect on reducing rotavirus-induced diarrhea among unvaccinated persons, thereby suggesting the induction of herd immunity. The U.S. Advisory Committee on Immunization Practices (Chapter 15) and the World Health Organization now recommend the routine use of these vaccines.

Currently several other rotavirus vaccine formulations are being developed,[18] mostly to reduce costs, but like current vaccines are only about 50% efficacious against severe diseases in the poorest developing countries.[A5,A6] Even with this reduced effectiveness, however, licensed vaccines are still cost-effective in the less developed world.

TREATMENT

Because both norovirus and rotavirus disease resolves within days without treatment, the basic therapeutic goal is to prevent acute dehydration. The recommended oral rehydration salts solution, which now has an osmolarity of 331 mmol/L, is as effective as higher-osmolarity solutions. After rehydration, rapid age-appropriate refeeding is recommended. Rotavirus disease induces self-limited intestinal lactase deficiency, but lactose-containing products, particularly maternal milk, should not be withheld.

Passive oral immunotherapy with diverse preparations of immunoglobulins can shorten the duration of rotavirus infection but probably is economically feasible only for immunodeficient patients or low-birthweight infants in the developed world. Recently in Bangladesh, a llama-derived, heavy-chain antibody fragment specific for rotavirus was able to reduce stool output in male infants with severe rotavirus-associated diarrhea. *Lactobacillus*, a bacterium present in yogurt, is safe and, in some, but not all, studies[A7] has been moderately effective for treatment of acute rotavirus gastroenteritis. Nonetheless, different preparations of lactobacilli vary greatly in dose of bacteria, and a general recommendation on their use has not been issued. Several studies in developing countries have shown that zinc supplementation (10 mg/day for infants younger than 6 months and 20 mg/day for older children) is useful for the treatment and prevention of diarrhea, but further studies are needed to determine whether treatment will be useful in all developing and developed countries.

At present, no pharmacologic treatment of rotavirus or norovirus diarrhea is recommended. Racecadotril (4.5 mg/kg per day), an enkephalinase inhibitor that acts on the enteric nervous system, has been shown to be useful as an

adjunct to treat rotaviral diarrhea in some, but not all, studies. Ondansetron (0.15 mg/kg per day), a serotonin antagonist, is effective in reducing the emesis from gastroenteritis during the phase of oral rehydration.[A8] In several small studies, nitazoxanide (15 mg/kg per day) was helpful in the treatment of rotavirus gastroenteritis.[A9] More studies are needed before any of these various preparations can be generally recommended for treatment of rotavirus diarrhea.

351 VIRAL HEMORRHAGIC FEVERS

DANIEL G. BAUSCH AND LAURENT KAISER

DEFINITION

Viral hemorrhagic fever is an acute systemic illness classically involving fever, a constellation of initially nonspecific signs and symptoms, and a propensity for bleeding and shock.

The Pathogens

Viral hemorrhagic fever may be caused by more than 30 different viruses from four taxonomic families, Filoviridae, Arenaviridae, Bunyaviridae, and Flaviviridae (Table 351-1), but not every virus in these families causes the syndrome. Recently discovered viruses such as severe fever with thrombocytopenia and heartland viruses (family Phenuiviridae family)[1] have variably been considered as hemorrhagic fever viruses, thereby highlighting the extreme heterogeneity and perhaps increasing ambiguity of this categorization. All implicated viruses are single-stranded lipid-enveloped RNA viruses with small genomes (10 to 19 kilobases) that can be relatively easily inactivated in the environment.

EPIDEMIOLOGY

Maintenance in Nature and Transmission to Humans

With the exception of dengue virus, for which humans can now be considered the reservoir, all hemorrhagic fever viruses are zoonotic, maintained in nature in mammalian reservoirs that tend to be specific for each virus (see Table 351-1). Although viral hemorrhagic fevers collectively can be found worldwide, the endemic area of any given hemorrhagic fever virus is usually smaller than the extent of its natural reservoir or arthropod vector. With the exception of dengue, yellow fever, and some hantaviruses, human infection is generally infrequent and humans are usually dead-end hosts.

Depending upon the virus, primary transmission to humans may be from contact with infected animal excreta or other body fluids or from the bite of an arthropod vector. Infection may occur through direct exposure of mucous membranes or broken skin to the infected blood or excreta of an animal reservoir, which usually occurs inadvertently or, in the case of the flaviviruses and most of the bunyaviruses, by the bite of an arthropod vector. Transmissibility between humans and pathogenicity vary with the specific virus and sometimes even among strains of the same virus. The infectious dose for most hemorrhagic fever viruses appears to be low, sometimes on the order of just a few virions. Airborne transmission is not a predominant mode of spread, if it occurs at all; however, studies in nonhuman primates show that transmission of many hemorrhagic fever viruses is possible through artificially created aerosols, thereby raising the possibility of their potential use as bioweapons (Chapter 19).

Bat-Borne Viruses

The filoviruses (from the Latin *filo*, "thread," referring to their filamentous shape), Marburg and Ebola, are perhaps the most feared of all hemorrhagic fever viruses.[2,3] Fruit bats appear to be the filovirus reservoir, although more conclusive evidence is needed for Ebola virus, with transmission to humans likely from exposure to infected bat excreta or saliva. Nonhuman primates, especially gorillas and chimpanzees, and other wild animals may become infected, presumably from similar bat exposure, and transmit filoviruses to humans through contact with blood and body fluids of these animals, usually in association with hunting. Nonhuman primates, which are also dead-end hosts who develop severe and usually fatal disease similar to that seen in humans, may be easier prey for hunters when sick. Because hemorrhagic fever viruses are rapidly inactivated by heating, infection probably occurs by exposure during butchering and preparation, rather than by consumption of cooked meat. The 2013 to 2016 outbreak of Ebola virus disease in West Africa dwarfed all prior Ebola outbreaks combined, with a reported 28,616 cases and 11,310 deaths. Sporadic outbreaks continue to occur in the Democratic Republic of the Congo, West Africa, and Uganda, either through primary infection from wild animals or renewed secondary infection from persistently infected humans (see later).

Rodent-Borne Viruses

Arenaviruses (from the Latin *arena*, "sand") are divided into Old World (or lymphocytic choriomeningitis/Lassa) and New World (or Tacaribe) complexes. Lassa and Lujo viruses are found in Africa, whereas Junín, Machupo, Guanarito, Sabiá, and Chapare viruses are found in South America. Although there may be subtle differences among the syndromes produced by the New World arenaviruses, they are usually grouped together simply as the South American hemorrhagic fevers.

The genus Hantavirus of the Bunyaviridae family is similarly divided into Old and New World complexes. The Old World hantaviruses, such as Hantaan, Seoul, and Puumala, among many others, classically cause hemorrhagic fevers with prominent renal involvement across Europe and Asia. New World hantaviruses, such as Sin Nombre and Andes, among many others, cause hantavirus pulmonary syndrome, sometimes also called hantavirus cardiopulmonary syndrome to emphasize the significant cardiogenic component of this disease.

Pathogenic arenaviruses and hantaviruses are maintained in nature through chronic subclinical infection in rodents of the Muridae family, with a strict pairing between the specific virus and rodent species. Transmission between rodents may be by vertical or horizontal transmission or both, depending on the specific virus. Transmission to humans occurs through exposure to rodent excreta, either from aerosols produced when rodents urinate or by direct inoculation to the mucous membranes, although the precise modes of transmission remain to be elucidated. Secondary aerosol generation is notoriously inefficient, so disturbing shed urine is a less likely mechanism of infection. In West Africa, Lassa virus is sometimes contracted when rodents are trapped and prepared for consumption or, more rarely, through a rodent bite. Experimental data suggest that humans may also be infected with arenaviruses by the oral route.

The rodents that transmit Lassa, Machupo, and many of the Old World hantaviruses commonly invade the peridomestic environment, thereby putting housewives, children, and others who spend time at home at risk. In contrast, the reservoirs for Junín and Guanarito viruses, as well as most

adjunct to treat rotaviral diarrhea in some, but not all, studies. Ondansetron (0.15 mg/kg per day), a serotonin antagonist, is effective in reducing the emesis from gastroenteritis during the phase of oral rehydration.[A8] In several small studies, nitazoxanide (15 mg/kg per day) was helpful in the treatment of rotavirus gastroenteritis.[A9] More studies are needed before any of these various preparations can be generally recommended for treatment of rotavirus diarrhea.

351 VIRAL HEMORRHAGIC FEVERS

DANIEL G. BAUSCH AND LAURENT KAISER

DEFINITION

Viral hemorrhagic fever is an acute systemic illness classically involving fever, a constellation of initially nonspecific signs and symptoms, and a propensity for bleeding and shock.

The Pathogens

Viral hemorrhagic fever may be caused by more than 30 different viruses from four taxonomic families, Filoviridae, Arenaviridae, Bunyaviridae, and Flaviviridae (Table 351-1), but not every virus in these families causes the syndrome. Recently discovered viruses such as severe fever with thrombocytopenia and heartland viruses (family Phenuiviridae family)[1] have variably been considered as hemorrhagic fever viruses, thereby highlighting the extreme heterogeneity and perhaps increasing ambiguity of this categorization. All implicated viruses are single-stranded lipid-enveloped RNA viruses with small genomes (10 to 19 kilobases) that can be relatively easily inactivated in the environment.

EPIDEMIOLOGY

Maintenance in Nature and Transmission to Humans

With the exception of dengue virus, for which humans can now be considered the reservoir, all hemorrhagic fever viruses are zoonotic, maintained in nature in mammalian reservoirs that tend to be specific for each virus (see Table 351-1). Although viral hemorrhagic fevers collectively can be found worldwide, the endemic area of any given hemorrhagic fever virus is usually smaller than the extent of its natural reservoir or arthropod vector. With the exception of dengue, yellow fever, and some hantaviruses, human infection is generally infrequent and humans are usually dead-end hosts.

Depending upon the virus, primary transmission to humans may be from contact with infected animal excreta or other body fluids or from the bite of an arthropod vector. Infection may occur through direct exposure of mucous membranes or broken skin to the infected blood or excreta of an animal reservoir, which usually occurs inadvertently or, in the case of the flaviviruses and most of the bunyaviruses, by the bite of an arthropod vector. Transmissibility between humans and pathogenicity vary with the specific virus and sometimes even among strains of the same virus. The infectious dose for most hemorrhagic fever viruses appears to be low, sometimes on the order of just a few virions. Airborne transmission is not a predominant mode of spread, if it occurs at all; however, studies in nonhuman primates show that transmission of many hemorrhagic fever viruses is possible through artificially created aerosols, thereby raising the possibility of their potential use as bioweapons (Chapter 19).

Bat-Borne Viruses

The filoviruses (from the Latin *filo*, "thread," referring to their filamentous shape), Marburg and Ebola, are perhaps the most feared of all hemorrhagic fever viruses.[2,3] Fruit bats appear to be the filovirus reservoir, although more conclusive evidence is needed for Ebola virus, with transmission to humans likely from exposure to infected bat excreta or saliva. Nonhuman primates, especially gorillas and chimpanzees, and other wild animals may become infected, presumably from similar bat exposure, and transmit filoviruses to humans through contact with blood and body fluids of these animals, usually in association with hunting. Nonhuman primates, which are also dead-end hosts who develop severe and usually fatal disease similar to that seen in humans, may be easier prey for hunters when sick. Because hemorrhagic fever viruses are rapidly inactivated by heating, infection probably occurs by exposure during butchering and preparation, rather than by consumption of cooked meat. The 2013 to 2016 outbreak of Ebola virus disease in West Africa dwarfed all prior Ebola outbreaks combined, with a reported 28,616 cases and 11,310 deaths. Sporadic outbreaks continue to occur in the Democratic Republic of the Congo, West Africa, and Uganda, either through primary infection from wild animals or renewed secondary infection from persistently infected humans (see later).

Rodent-Borne Viruses

Arenaviruses (from the Latin *arena*, "sand") are divided into Old World (or lymphocytic choriomeningitis/Lassa) and New World (or Tacaribe) complexes. Lassa and Lujo viruses are found in Africa, whereas Junín, Machupo, Guanarito, Sabiá, and Chapare viruses are found in South America. Although there may be subtle differences among the syndromes produced by the New World arenaviruses, they are usually grouped together simply as the South American hemorrhagic fevers.

The genus Hantavirus of the Bunyaviridae family is similarly divided into Old and New World complexes. The Old World hantaviruses, such as Hantaan, Seoul, and Puumala, among many others, classically cause hemorrhagic fevers with prominent renal involvement across Europe and Asia. New World hantaviruses, such as Sin Nombre and Andes, among many others, cause hantavirus pulmonary syndrome, sometimes also called hantavirus cardiopulmonary syndrome to emphasize the significant cardiogenic component of this disease.

Pathogenic arenaviruses and hantaviruses are maintained in nature through chronic subclinical infection in rodents of the Muridae family, with a strict pairing between the specific virus and rodent species. Transmission between rodents may be by vertical or horizontal transmission or both, depending on the specific virus. Transmission to humans occurs through exposure to rodent excreta, either from aerosols produced when rodents urinate or by direct inoculation to the mucous membranes, although the precise modes of transmission remain to be elucidated. Secondary aerosol generation is notoriously inefficient, so disturbing shed urine is a less likely mechanism of infection. In West Africa, Lassa virus is sometimes contracted when rodents are trapped and prepared for consumption or, more rarely, through a rodent bite. Experimental data suggest that humans may also be infected with arenaviruses by the oral route.

The rodents that transmit Lassa, Machupo, and many of the Old World hantaviruses commonly invade the peridomestic environment, thereby putting housewives, children, and others who spend time at home at risk. In contrast, the reservoirs for Junín and Guanarito viruses, as well as most

ABSTRACT

Viral hemorrhagic fever is an acute systemic febrile syndrome caused by over 30 viruses from four different virus families, although not all infections result in the syndrome. Microvascular instability with capillary leak and impaired hemostasis are the pathogenic hallmarks, but the mechanisms that result in these phenomena vary widely, depending on the virus. The syndrome is characterized by a short incubation period (usually 1 to 2 weeks) followed by a rapidly progressive multisystem illness that typically persists for no longer than 2 weeks. Initial signs and symptoms are usually nonspecific and include fever, headache, and myalgia, followed rapidly by gastrointestinal symptoms (nausea, vomiting and diarrhea) and, in some cases, rash and neurologic involvement. Severe cases develop hemodynamic instability, bleeding, shock, and multiorgan system dysfunction. Case-fatality rates range from less than 1% to over 80% depending on the specific infecting virus. With the exception of dengue, the causative viruses are all zoonotic, with endemic areas limited to the distribution of their mammalian reservoirs and/or arthropod vectors. Imported cases are rare but increasingly reported. The initial nonspecific manifestations of the syndrome make clinical diagnosis of isolated cases challenging. Viral hemorrhagic fever should be considered in febrile patients with a compatible clinical syndrome and history of travel and exposure. Although many hemorrhagic fever viruses may be spread person-to-person via contact with infected body fluids, secondary attack rates are generally low when routine universal precautions are maintained. For added safety, specialized viral hemorrhagic fever precautions are warranted when a confirmed or highly suspicious index case is identified. Treatment of viral hemorrhagic fever is generally supportive, but recent clinical trials have shown promising results for the treatment of Ebola virus disease. The antiviral drug ribavirin may be indicated for Lassa and other arenavirus infections, although more definitive evidence of efficacy is needed. Safe and effective vaccines exists for yellow fever and have been recently approved for Ebola virus disease.

TABLE 351-1 PRINCIPAL VIRUSES CAUSING HEMORRHAGIC FEVER

FAMILY AND VIRUS	DISEASE	GEOGRAPHIC DISTRIBUTION OF DISEASE	PRINCIPAL RESERVOIR/ VECTOR	ANNUAL ESTIMATED CASES	CASE-TO-INFECTION RATIO	HUMAN-TO-HUMAN TRANSMISSIBILITY
FILOVIRIDAE						
Ebola virus	Ebola virus disease	Central and West Africa	Fruit bat?	—*	1 : 1	High
Marburg virus	Marburg virus disease	Sub-Saharan Africa	Egyptian fruit bat *(Rousettus aegyptiacus)*	—*	1 : 1	High
ARENAVIRIDAE†,‡						
Old World Group						
Lassa	Lassa fever	West Africa	Rodent: natal mastomys or multimammate rat *(Mastomys natalensis)*	50,000-100,000	1 : 5-10	Moderate
Lujo§	Lujo HF	Zambia	Unknown, presumed rodent	Unknown	Unknown	Moderate to high
New World Group						
Junín	Argentine HF	Argentine pampas	Rodent: corn mouse *(Calomys musculinus)*	≈100	1 : 1.5	Low
Machupo	Bolivian HF	Beni Department, Bolivia	Rodent: large vesper mouse *(Calomys callosus)*	≤50	1 : 1.5	Low
Guanarito	Venezuelan HF	Portuguesa State, Venezuela	Rodent: cane mouse *(Zygodontomys brevicauda)*	≤50	1 : 1.5	Low
Sabiá‖	Brazilian HF	São Paulo and Para States, Brazil	Unknown, presumed rodent	Unknown	1 : 1.5	Low?
Chapare¶	Chapare HF	Cochabamba and La Paz Departments, Bolivia	Unknown, presumed rodent	Unknown	Unknown	Unknown
BUNYAVIRIDAE†						
Old World Complex						
Hantaan, Seoul, Puumala, Dobrava-Belgrade, others	HF with renal syndrome	Hantaan: northeast Asia. Seoul: urban areas worldwide Puumala and Dobrava-Belgrade: Europe	Rodent Hantaan: striped field mouse *(Apodemus agrarius)* Seoul: brown or Norway rat *(Rattus norvegicus)* Puumala: bank vole *(Clethrionomys glareolus)* Dobrava-Belgrade: yellow-necked field mouse *(Apodemus flavicollis)*	50,000-150,000	Hantaan: 1 : 1.5 Others: 1 : 20	None
New World Complex						
Sin Nombre, Andes, Laguna Negra, others	Hantavirus pulmonary syndrome	Americas	Rodent Sin Nombre: deer mouse *(Peromyscus maniculatus)* Andes: long-tailed colilargo *(Oligoryzomys longicaudatus)* Laguna Negra: little laucha or small vesper mouse *(Calomys laucha)*	50,000-150,000	Sin Nombre: 1 : 1 Others: up to 1 : 20	None, except for Andes virus
Rift Valley fever	Rift Valley fever	Sub-Saharan Africa, Madagascar, Saudi Arabia, Yemen	Domestic livestock/ mosquitoes (sylvatic *Aedes* and others)	100-100,000*,**	1 : 100	None
Crimean-Congo HF	Crimean-Congo HF	Africa, Balkans, southern Russia, Middle East, India, Pakistan, Afghanistan, western China	Wild and domestic vertebrates/tick (primarily *Hyalomma* species)	≈500	1 : 1-2	High
FLAVIVIRIDAE						
Yellow fever	Yellow fever	Sub-Saharan Africa, South America up to Panama	Monkey/mosquito (*Aedes aegypti*, other *Aedes* and *Haemagogus* species)	5,000-200,000††	1 : 2-20	None
Dengue	Dengue HF	Tropics and subtropics worldwide	Human/mosquito (*A. aegypti* and *albopictus*)	100,000-200,000††	1 : 10-100, depending on age, previous infection, genetic background, and infecting serotype	None
Omsk HF	Omsk HF	Western Siberia	Rodent/tick (primarily *Dermacentor* and *Ixodes* species)	100-200	Unknown	Not reported

TABLE 351-1 PRINCIPAL VIRUSES CAUSING HEMORRHAGIC FEVER—cont'd

FAMILY AND VIRUS	DISEASE	GEOGRAPHIC DISTRIBUTION OF DISEASE	PRINCIPAL RESERVOIR/ VECTOR	ANNUAL ESTIMATED CASES	CASE-TO-INFECTION RATIO	HUMAN-TO-HUMAN TRANSMISSIBILITY
Kyasanur Forest disease	Kyasanur Forest disease	Karnataka state, India; Yunnan Province, China; Saudi Arabia	Vertebrate (rodents, bats, birds, monkeys, others)/ tick (*Haemaphysalis* species and others)	≈500	Unknown	Not reported, but laboratory infections have occurred
Alkhumra HF‡‡	Proposed name: Alkhumra HF	Saudi Arabia, Egypt	Ticks?	≤50	Unknown	Not reported

*Although some endemic transmission of the filoviruses (Ebola virus > Marburg virus) and Rift Valley fever virus occurs, these viruses are most often associated with outbreaks.
†The virus families *Arenaviridae* and *Bunyaviridae* are serologically, phylogenetically, and geographically divided into Old World (i.e., Africa and Asia) and New World (i.e., the Americas) complexes.
‡In addition to the arenaviruses listed in the table, Flexal and Tacaribe viruses have caused human disease as a result of laboratory accidents. Another arenavirus, Whitewater Arroyo, has been noted in sick persons in California, but its role as a pathogen has not been clearly established.
§Only five cases (four of them fatal) from one outbreak in 2008 have been noted. The index case came to South Africa from Zambia.
‖Only five cases (three fatal) have been noted, two of them from laboratory accidents.
¶Discovered from a small outbreak in 2003 from which blood was obtained from one fatal case and Chapare virus isolated. Few other details have been reported. A cluster of five cases, three fatal, occurred on the outskirts of La Paz, Bolivia, in 2019.
**Although Rift Valley fever virus can be found throughout sub-Saharan Africa, large outbreaks usually occur in East Africa's Rift Valley region.
††Based on estimates from the World Health Organization. Significant underreporting occurs. Incidence may fluctuate widely in place and time.
‡‡Alkhumra is considered by some to be a variant of Kyasanur Forest disease virus. Disagreement exists over the proper spelling of the virus, written as Alkhurma in some publications.
HF = hemorrhagic fever.

of the New World hantaviruses, typically inhabit agricultural fields, wood lots, or other rural habitats, thereby putting outdoor workers, campers, and hikers at risk.

Mosquito-Borne Viruses

Rift Valley fever virus is maintained in domestic livestock, such as cattle, buffalo, sheep, goats, and camels, in which it often provokes spontaneous abortion. The virus may be transmitted to humans by direct exposure to these animals, especially during parturition, or by mosquitoes. Farmers, abattoir workers, and veterinarians are at particular risk.[4]

Yellow fever virus is maintained in a cycle between monkeys and forest canopy mosquitoes. Sporadic cases occur when humans are bitten by these mosquitoes, known as the sylvatic or jungle cycle. Larger outbreaks occur when humans bring the virus back to more settled environments, where the urban mosquito *Aedes aegypti* can spread the virus directly between humans (the urban cycle). *Aedes aegypti*, which typically lay eggs in artificial containers around the home and bite during the day, become infective a few weeks after feeding on a viremic monkey or human. An estimated 90% of infections occur on the African continent,[5] but large outbreaks have also been seen in South America in recent years, thereby prompting mass vaccination campaigns of millions of people and occasionally resulting in exported cases. Although *Aedes aegypti*, mosquitoes are commonly found across Asia, the Pacific, and Australia, endogenous transmission of yellow fever virus has never been recorded in these locations for unknown reasons.

Although nonhuman primates are also a reservoir for sylvatic strains of dengue, the virus is now adapted and maintained in humans, with a regular transmission cycle akin to that of urban yellow fever. Dengue virus is found in the tropics and subtropics nearly worldwide. The incidence of infection has grown dramatically in recent decades, especially in Asia and Latin America. Less than 10% of infected persons develop hemorrhagic fever, primarily children between the ages of 4 and 12 years.

Tick-Borne Viruses

The viruses that cause Crimean-Congo hemorrhagic fever,[6] Omsk hemorrhagic fever, Kyasanur Forest disease, and Alkhumra hemorrhagic fever are maintained in small mammals, such as rodents, hares, and hedgehogs, among which the viruses are spread by ticks. Humans are infected either by tick bites or by exposure to contaminated blood or excreta of the reservoir animals. Ticks also spread Crimean-Congo hemorrhagic fever virus to large mammals, including cattle and other domestic livestock, whose transient and asymptomatic viremia puts farmers, abattoir workers, and veterinarians at risk.

Human-to-Human Transmission

Secondary human-to-human transmission occurs with many of the hemorrhagic fever viruses (see Table 351-1), but attack rates are generally low (less than 15% for Ebola Zaire virus) because transmission between humans requires direct contact with contaminated blood or body fluids. Nevertheless, as evidenced by the massive 2013 to 2016 outbreak of Ebola virus disease in West Africa, the risk of transmission can increase significantly when many sick patients overwhelm fragile health systems and infection prevention and control measures break down, especially when health care workers are insufficiently trained and equipped. Human-to-human transmission probably usually occurs through oral or mucous membrane exposure, most often in the context of providing care to a sick family member (community) or patient (nosocomial transmission). Funeral rituals that entail the touching of the corpse have been a major source of infection in some outbreaks. Infection through fomites cannot be excluded. In some cases, highly infectious "super spreaders" have been suspected, but there is no evidence for natural aerosol transmission between humans. Despite modern-day travel, imported cases of viral hemorrhagic fever remain infrequent and usually do not result in secondary transmission because of the more routinely maintained infection prevention and control practices in resource-rich countries.

With the exception of hantaviruses and some of the flaviviruses, infectivity parallels the clinical state; persons are most infectious late in the course of severe disease, when viral loads are high and patients shed virus into the environment through vomiting, diarrhea, and bleeding. The risk of transmission during the incubation period or from asymptomatic persons is negligible, although a case of Argentine hemorrhagic fever occurred after blood transfusion from a donor who was asymptomatic at the time the blood was taken.

PATHOBIOLOGY

Microvascular instability and impaired hemostasis are the pathobiologic hallmarks of viral hemorrhagic fever. However, not all infections lead to these conditions, which are seen only in a subset of patients at the severe end of the disease spectrum.[7]

With the exception of disease caused by the hantaviruses and some of the flaviviruses, the pathogenesis of viral hemorrhagic fever appears to be related to unchecked viremia, with most fatal cases failing to mount an effective immune response. In these diseases, infectious virus is cleared rapidly from the blood in survivors. In dengue, yellow fever, and hantavirus infections, by comparison, viral replication is usually controlled, and virus is cleared from the blood before the most severe phase of the disease. The unique process of antibody-mediated immune enhancement, in which secondary infection with a different dengue virus serotype is more severe than the primary one, may play a role in the pathogenesis of dengue hemorrhagic fever. Data from animal models suggest that cardiac inotropy may also be directly or indirectly inhibited in some viral hemorrhagic fevers, especially Lassa fever.

After inoculation, virus first replicates in dendritic cells and other local tissues, with subsequent migration to regional lymph nodes and then

dissemination through the lymph and blood monocytes to a broad range of tissues and organs, including the liver, spleen, lymph nodes, adrenal glands, lungs, and endothelium. Migration of tissue macrophages results in secondary infection of permissive parenchymal cells. During the acute illness, virus can be found in a wide variety of body fluids, including blood, saliva, stool, and breast milk.

The interaction of virus with immune cells, especially macrophages and endothelial cells, results directly or indirectly (through soluble mediators) in cell activation and the unleashing of an inflammatory and vasoactive process consistent with the systemic inflammatory response syndrome. The synthesis of cell surface tissue factor triggers the extrinsic coagulation pathway. Impaired hemostasis may entail endothelial cell, platelet, or coagulation factor dysfunction. Disseminated intravascular coagulopathy (DIC; Chapter 161) is frequently noted, especially with Ebola, Marburg, and Crimean-Congo hemorrhagic fever viruses.

Inflammatory cell infiltrates, which are usually mild, consist of a mix of mononuclear cells and neutrophils. In some viral hemorrhagic fevers, such as Ebola virus disease, virus replication and dissemination are facilitated by virus-induced suppression of the host adaptive immune response. Failure of the immune response to adequately respond appears to be a major determinant of severity in Lassa fever.

Tissue damage may be mediated through direct necrosis of infected cells or indirectly through apoptosis of immune cells, as seen in other forms of septic shock. A dysregulated and uncontrolled host immune response leads to end-organ damage, with the most affected organs varying with the virus (Table 351-2). For example, renal tubular necrosis and retroperitoneal edema are seen in hemorrhagic fever with renal syndrome, whereas interstitial pneumonitis and myocardial depression are the hallmarks of hantavirus pulmonary syndrome. The liver is particularly affected in yellow fever, with fatty degeneration, coagulative midzonal necrosis of hepatocytes, and the presence of Councilman bodies. The brain and meninges are particularly affected in Kyasanur Forest disease and Omsk hemorrhagic fever and often in the South American hemorrhagic fevers as well. Reticuloendothelial proliferation is seen in Kyasanur Forest disease, with marked erythrophagocytosis in the spleen.

CLINICAL MANIFESTATIONS

Viral hemorrhagic fever is seen in both genders and all age groups, with a spectrum from relatively mild or even asymptomatic infection to severe vascular permeability resulting in shock, multiorgan system failure, and death. Although the clinical presentation may differ for each viral hemorrhagic fever as the disease progresses, clinical manifestations do not permit clear distinctions in most cases, especially in the early phases of disease. Dengue and Rift Valley fever viruses cause a range of syndromes, including rash and central nervous system involvement (Chapter 352). Hemorrhagic fever occurs in a minority of infections with these viruses.

After an incubation period ranging from days to weeks, most patients present with nonspecific signs and symptoms that are difficult to distinguish from many other febrile illnesses (see Table 351-2), including fever, general malaise, anorexia, headache, chest or retrosternal pain, sore throat, myalgia, arthralgia, and lumbosacral pain.[8] Conjunctival injection or hemorrhage is frequent but is not accompanied by itching, discharge, or rhinitis, thereby helping to distinguish it from viral conjunctivitis (Fig. 351-1). Relative bradycardia (Faget sign) and orthostatic hypotension may be noted, especially in yellow fever and dengue virus infections. The pharynx may be erythemic or, less frequently, exudative, especially in Lassa fever, and incorrectly lead to a diagnosis of streptococcal pharyngitis or mononucleosis. Hiccups are often seen in Ebola virus disease, although the pathogenesis of this manifestation is unclear.

After the first few days, gastrointestinal signs and symptoms readily ensue, including nausea, vomiting, epigastric and abdominal pain, abdominal tenderness, and nonbloody diarrhea or constipation. A misdiagnosis of appendicitis or other acute abdominal emergency (Chapter 128) sometimes prompts potentially hazardous surgical interventions.

Neck pain and stiffness, retro-orbital pain, photophobia, and other meningeal signs are common in Rift Valley fever, Kyasanur Forest disease, and Omsk hemorrhagic fever. A dry cough, sometimes accompanied by a few scattered rales on auscultation, is common, but prominent pulmonary symptoms are uncommon early in the course of the disease, except with hantavirus pulmonary syndrome. With the exception of yellow fever, jaundice is not typical except in patients with underlying Gilbert syndrome, drug reactions, or coinfection. Hepatosplenomegaly is frequent, but whether it is specific to the viral hemorrhagic fever or simply represents the high underlying prevalence of hepatosplenomegaly in populations in sub-Saharan Africa is unknown.

Various forms of rash, including morbilliform, maculopapular, petechial, and ecchymotic, may be seen (see Table 351-2). A maculopapular rash on the torso or face may be one early and relatively specific but insensitive indicator of Ebola or Marburg virus disease. Rash almost always occurs in fair-skinned persons with Lassa fever and Lujo hemorrhagic fever but, for unclear reasons, rarely in Blacks.

Hemorrhage is almost never present in the first few days of illness. In severe cases, however, patients progress after 7 to 10 days of illness to vascular instability, which may be manifested by conjunctival injection and hemorrhage, facial flushing, edema, bleeding, hypotension, shock, and proteinuria. Facial and neck swelling are classic and relatively specific signs of Lassa fever and Lujo hemorrhagic fever.

Sophisticated surveillance and detection methods show that clinically discernable bleeding occurs in a minority of cases, and the likelihood of hemorrhage varies with the infecting virus (see Table 351-2). Hemorrhage may be manifested as hematemesis, melena, hematochezia, metrorrhagia, petechiae, purpura, epistaxis, and bleeding from the gums and venipuncture sites (Fig. 351-2). Hemoptysis and hematuria are infrequent. Large ecchymoses are characteristic of Crimean-Congo hemorrhagic fever.

Central nervous system manifestations, including delirium, tremor, gait anomalies, convulsions, and hiccups, may be noted in end-stage disease, especially in Kyasanur Forest disease, Omsk hemorrhagic fever, and the South American hemorrhagic fevers, particularly Argentine hemorrhagic fever. Nevertheless, the cerebrospinal fluid findings are usually normal, with the exception of patients who have meningoencephalitis due to Kyasanur Forest disease or Omsk hemorrhagic fever, in which an elevated protein level is common.

Pancreatitis is often seen in severe yellow fever. Renal insufficiency or failure, which is common especially in hemorrhagic fever with renal syndrome, Lassa fever, and Ebola virus disease, is associated with a poor prognosis.

Biphasic illnesses are classically noted for the flavivirus hemorrhagic fevers, in which a quiescent period of days (yellow fever, dengue hemorrhagic fever, and Rift Valley fever) to weeks (Kyasanur Forest disease and Omsk hemorrhagic fever) precedes the most severe manifestations, including hemorrhage, shock, renal failure, and meningoencephalitis. Distinct progressive phases are classically described for hemorrhagic fever with renal syndrome (prodrome, hypotension, oliguria/renal failure, diuresis, and convalescence) and yellow fever (infection, intoxication, recovery) but are not seen in all cases. The initial manifestations for hantavirus pulmonary syndrome may be mild and nonspecific, but the disease may progress to require mechanical ventilation and pressor support within 24 hours. Sinus bradycardia and ventricular tachycardia or fibrillation may occur. Encephalitis and retinitis may develop in Rift Valley fever independently of the presence or absence of viral hemorrhagic fever.

Bilateral noncardiogenic interstitial pulmonary edema consistent with the adult respiratory distress syndrome (ARDS) is the hallmark of hantavirus pulmonary syndrome, although chest radiographs may be normal early in the disease even when the patients complain of shortness of breath. Only about 30% of patients with hantavirus pulmonary syndrome have radiographic evidence of pulmonary edema on initial evaluation, although it develops in virtually all persons within 48 hours.

Pregnant women with viral hemorrhagic fever usually present with severe disease, including spontaneous abortion and vaginal bleeding. However, initially mild symptoms that nevertheless progress to severe and even fatal disease have been noted, perhaps because the immune tolerance of pregnancy dampens the initial inflammatory clinical manifestations.

DIAGNOSIS

Because of their associated severity, risk of secondary spread, high degree of public scrutiny, and unfamiliarity to most physicians, consultation with a specialist who has experience with viral hemorrhagic fevers should be sought as soon as the diagnosis is considered. When to "sound the alarm" of viral hemorrhagic fever is a case-by-case decision left to the treating physician in consultation with experts in the field. Most viral hemorrhagic fevers are rare, and routinely practiced universal precautions are protective in most cases, at least in the early phases of disease.

TABLE 351-2 PATHOBIOLOGIC AND CLINICAL ASPECTS OF VIRAL HEMORRHAGIC FEVERS

DISEASE	INCUBATION PERIOD (DAYS)	ONSET	BLEEDING	RASH	JAUNDICE	HEART	LUNG	KIDNEY	CENTRAL NERVOUS SYSTEM	EYE	CASE-FATALITY RATIO	CLINICAL MANAGEMENT
FILOVIRIDAE												
Ebola virus disease	3-21	Variable	++	+	+	+	+	+	+	++*	40-85%†	Monoclonal antibodies

*Potentially sight-threatening uveitis, early cataract formation, and other ocular sequelae are noted in up to one third of survivors.

†Four species of Ebola virus are known to cause disease in humans, with varying associated case-fatality ratios during outbreaks: Zaire, 85%; Sudan, 55%; Bundibugyo, 40%; and Tai Forest (formerly Côte d'Ivoire), 0% (only one recognized case, who survived).

‡The case-fatality ratio was 22% in the first recognized outbreak of Marburg virus disease in Germany and Yugoslavia in 1967 but has been consistently above 80% in outbreaks in central Africa, where the virus is endemic. Possible reasons for this discrepancy include differences in quality of care, strain pathogenicity, route and dose of infection, underlying prevalence of immunodeficiency and comorbid illnesses, and genetic susceptibility.

§A morbilliform or maculopapular rash almost always occurs in persons with lighter skin, who are usually expatriates, but for unclear reasons is rarely present in darker-skinned Africans from the endemic area.

‖Data are insufficient to distinguish between the syndromes produced by the various arenaviruses found in the Americas. They are thus frequently grouped as the South American hemorrhagic fevers.

¶Hemorrhagic fever, encephalitis, and retinitis may be seen in Rift Valley fever independently of each other.

**The incubation period of Crimean-Congo HF varies with the mode of transmission: typically 1 to 3 days after tick bite and 5 to 6 days after contact with infected animal blood or tissues.

††Based on preliminary observations. Fewer than 100 cases have been reported.

ECMO = extracorporeal membrane oxygenation; HF = hemorrhagic fever; 0 = sign not typically noted/organ not typically affected; + = sign occasionally noted/organ occasionally affected; ++ = sign commonly noted/organ commonly affected; +++ = sign characteristic/organ involvement severe.

The early nonspecific presentation of viral hemorrhagic fevers makes them extremely difficult to diagnose clinically, especially outside of the setting of a recognized outbreak, which is usually detected when clusters of cases occur, especially when they involve health care workers. The differential diagnosis includes a broad array of febrile illnesses that varies by geographic region (Table 351-3). A complete epidemiologic history (including details of travel, possible exposures, and occupational risks), details of the evolution of symptoms, physical examination, and preliminary basic laboratory results (Table 351-4) are critical.

A diagnosis of viral hemorrhagic fever should be considered in patients with a clinically compatible syndrome who, within the incubation period for the particular viral hemorrhagic fever in question, (1) reside in or traveled to an endemic area (see Table 351-1); (2) had potential direct contact with blood or body fluids of someone who was ill with an acute viral hemorrhagic fever, such as health care workers, persons caring for family members at home or preparing bodies for burial, and laboratory personnel; (3) had contact with live or recently killed wild animals (especially nonhuman primates) in or recently arriving from an area where a viral hemorrhagic fever is endemic (although direct contact with the animal reservoir is not usually reported even in confirmed cases); (4) worked in a laboratory or animal facility where hemorrhagic fever viruses are handled; or (5) had unprotected sex with a male who recovered from a viral hemorrhagic fever in the prior 18 months, unless his semen has been tested by polymerase chain reaction (PCR) and confirmed negative.

The index of suspicion should be especially high for persons in specific high-risk occupations, including health care workers, abattoir workers, veterinarians, farmworkers, hunters, taxidermists, and travelers who have recently returned from endemic areas, especially if an ongoing or recent outbreak

FIGURE 351-1. Subconjunctival hemorrhage and facial swelling in a boy with Lassa fever in Sierra Leone.

FIGURE 351-2. Bleeding in a patient with Ebola virus disease. (From Bausch DG. Viral hemorrhagic fevers. In: Schlossberg D, ed. *Clinical Infectious Disease*. New York: Cambridge University Press; 2008.)

has been reported.[9] ARDS (Chapter 90) or other respiratory compromise in a person living in an endemic area for New World hantaviruses should prompt consideration of hantavirus pulmonary syndrome. Risk of tick infection, including physical examination for an eschar, should be assessed if a tick-borne viral hemorrhagic fever is suspected. However, most viral hemorrhagic fevers are rare even in persons possessing one of the risk factors, so alternative diagnoses should always be aggressively sought, especially endemic malaria and typhoid fever, but also other bacterial diseases, including gram-negative sepsis (Chapter 94). Acts of bioterrorism (Chapter 19) must be considered if viral hemorrhagic fever is strongly suspected in a patient without any of the aforementioned risk factors, especially if clusters of cases occur. All cases should be immediately reported to local, state, and federal health authorities.

Laboratory Testing

Prompt laboratory confirmation, preferably using PCR assays on blood specimens, is imperative.[10] PCR assays generally have sensitivities and specificities greater than 90%, although very few have been subject to formal product validation. Robust semi-automated cartridge-based assays may be useful for some viral hemorrhagic fevers during outbreaks, but their cost is generally prohibitive for routine surveillance. Some hemorrhagic fever viruses, such as Lassa, have considerable sequence heterogeneity, so false-negative PCR results can occur owing to primer-target mismatch. False-negative results may also occur if a patient is tested very early in the course of disease when virus levels may still be below the threshold of detection. If viral hemorrhagic fever is still suspected despite a negative test, the patient should be monitored, treated empirically as needed, and, if still ill, retested a few days later when, with the exception of flavivirus infections, the viral load would normally have risen to a detectable level. Unbiased high-throughput sequencing may be helpful if PCR is repeatedly negative.

Enzyme-linked immunosorbent assays for viral antigen and immunoglobulin M antibody, virus culture, and immunohistochemistry on postmortem tissues also generally have sensitivities and specificities greater than 90%, although serologic diagnosis of flavivirus infection is complicated by cross-reactions. Rapid antigen tests for Ebola virus disease have been used effectively for community surveillance of cadavers.[11] In the United States, viral hemorrhagic fever testing can be arranged through the Centers for Disease Control and Prevention (phone 470-312-0094; email spather@cdc.gov).

TREATMENT

The rarity of most viral hemorrhagic fevers and their typical occurrence in remote and resource-poor settings make controlled studies difficult. Treatment guidelines generally follow those recommended for septic shock (Chapter 94). Consensus guidelines for supportive care for Ebola virus disease include isolation in an intensive care unit where close monitoring and critical supportive care can be provided.[12,13]

Clinical Management Guidelines

Fluid and Electrolyte Management

Severe microvascular instability, often complicated by vomiting, diarrhea, and decreased fluid intake, typically requires aggressive fluid replacement and or vasopressor support to prevent shock and dangerous electrolyte imbalances (see Chapter 94). In some cases, voluminous diarrhea may be similar to that seen in cholera (Chapter 278). Most patients require intravascular fluid administration, with careful monitoring to avoid third-spacing and pulmonary edema, especially in hantavirus pulmonary syndrome.

Blood Products and Management of Disseminated Intravascular Coagulation

Blood products should not be given empirically but only to meet defined clinical and laboratory parameters in the face of clinically significant hemorrhage. Transfusions, preferably with packed red blood cells, should be used to maintain a hemoglobin concentration above 7.0 g/dL while avoiding volume overload, taking into account that chronic anemia due to malaria and malnutrition may be frequent in patients in certain geographic areas. Whole blood is a reasonable alternative if packed cells are not available.

The possibility of DIC (Chapter 161) should be assessed by the relevant laboratory parameters (see Table 351-4), such as D-dimer levels. Platelet transfusions are generally not given to patients with DIC unless serious hemorrhage is present. When given, the platelet count should generally rise by at least 5-10 $\times$ $10^3/\mu L$ per unit of platelets transfused, although the response may be less if there is ongoing DIC and platelet consumption. Impaired platelet aggregation may promote hemorrhage in some viral hemorrhagic fevers, especially Lassa fever, even when platelet counts are not drastically low. Transfusion of fresh-frozen plasma (FFP) (15 to 20 mL/kg) should be considered when bleeding is present and fibrinogen levels are less than 100 mg/dL. Fibrinogen concentrate (total dose of 2 to 3 g) or cryoprecipitate (1 U/10 kg) may be administered instead of FFP, although FFP has the theoretical advantage of containing all coagulation factors. Vitamin K (10 mg intravenously or orally on 3 consecutive days) may be given, especially if underlying malnutrition or liver disease is suspected. Folic acid has sometimes been added to prevent the detrimental effect of acute folate deficiency on platelet production, especially in malnourished patients, although the efficacy of this treatment is unknown.

TABLE 351-3 DIFFERENTIAL DIAGNOSIS OF THE VIRAL HEMORRHAGIC FEVERS

DISEASE	DISTINGUISHING CHARACTERISTICS AND COMMENTS
PARASITES	
Malaria	Classically shows paroxysms of fever and chills; hemorrhagic manifestations less common; malaria smears or rapid test result usually positive; coinfection (or baseline asymptomatic parasitemia) common; responds to antimalarials
Amebiasis	Hemorrhagic manifestations other than bloody diarrhea generally not seen; amebic trophozoites identified in the stool by microscopy or antigen assays; responds to antiparasitics
Giardiasis	Positive stool antigen test result or identification of trophozoites or cysts in stool; responds to antiparasitics
African trypanosomiasis (acute stages)	Especially the East African form; examination of peripheral blood smear/buffy coat may show trypanosomes
BACTERIA (INCLUDING SPIROCHETES, RICKETTSIA, EHRLICHIA, AND COXIELLA)	
Typhoid fever	Hemorrhagic manifestations other than bloody diarrhea generally not seen; responds to antibiotics
Bacillary dysentery (including shigellosis, campylobacteriosis, salmonellosis, and enterohemorrhagic *Escherichia coli* and others)	Hemorrhagic manifestations other than bloody diarrhea generally not seen; responds to antibiotics
Capnocytophaga canimorsus	Associated with dog and cat bites, typically in persons with underlying immunodeficiency, notably asplenic patients; responds to antibiotics
Meningococcemia	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; bleeding within the first 24-48 hours after onset of illness and rapidly progressive illness typical; large ecchymoses typical of meningococcemia are unusual in the VHFs except for Crimean-Congo HF; rapid serum latex agglutination tests can be used to detect bacterial antigen in meningococcal septicemia; may respond to antibiotics (critical to administer early)
Staphylococcemia	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; may respond to antibiotics
Septic abortion	History of pregnancy and positive pregnancy test
Septicemic or pneumonic plague	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; large ecchymoses typical of plague are unusual in the VHFs except for Crimean-Congo HF; pneumonic plague may mimic hantavirus pulmonary syndrome; may respond to antibiotics
Streptococcal or Epstein-Barr virus pharyngitis	May mimic the exudative pharyngitis sometimes seen in Lassa fever
Tuberculosis	Hemoptysis of advanced pulmonary tuberculosis may suggest VHF, but tuberculosis generally has a much slower disease evolution
Tularemia	Ulceroglandular and pneumonic forms more common; responds to antibiotics
Acute abdominal emergencies	Appendicitis, peritonitis, and bleeding upper gastrointestinal ulcer
Pyelonephritis and post-streptococcal glomerulonephritis	May mimic HF with renal syndrome
Anthrax (inhalation or gastrointestinal)	Prominent pulmonary manifestations and widened mediastinum on chest radiograph in inhalation form; responds to antibiotics
Atypical bacterial pneumonia (*Legionella*, *Mycoplasma*, *Chlamydophila pneumoniae*, and *C. psittaci*, others)	May mimic hantavirus pulmonary syndrome; exposure to birds; symptoms often not present until late in the illness in psittacosis; responds to antibiotics
Relapsing fever	Recurrent fevers and influenza-like symptoms, with direct neurologic involvement and splenomegaly; spirochetes visible in blood while febrile; responds to antibiotics
Leptospirosis	Jaundice, renal failure, and myocarditis in severe cases; responds to antibiotics
Spotted fever group rickettsiae (including African tick bite fever, boutonneuse fever, Rocky Mountain spotted fever)	Incubation period of 7-10 days after tick bite, compared with 1-3 days in Crimean-Congo HF; necrotic lesions (eschar) typically seen at site of tick bite in some rickettsial diseases, whereas there may be only slight bruising at the bite site in Crimean-Congo HF; rash (if present) of rickettsial infection classically involves palms and soles
Q fever (*Coxiella burnetii*)	Broad spectrum of illness, including hepatitis, pneumonitis, encephalitis, and multisystem disease with bleeding; responds to antibiotics
Ehrlichiosis	Diagnosis by serology and PCR; blood film may be useful; responds to antibiotics
Melioidosis (*Burkholderia pseudomallei*)	Highest incidence in Southeast Asia and northern Australia; systemic febrile illness or pulmonary syndrome, sometimes with central nervous system involvement; responds to antibiotics
VIRUSES	
Influenza	Prominent respiratory component to clinical presentation; no hemorrhagic manifestations; influenza rapid test result may be positive; may respond to anti-influenza drugs
Arbovirus infection (including dengue and West Nile fever)	Encephalitis unusual but when present may mimic the VHFs with significant neurologic involvement (Kyasanur Forest disease, Omsk HF); usually less severe than VHF; hemorrhage not reported
Viral hepatitis (including hepatitis A, B, and E; Epstein-Barr; and cytomegalovirus)	Jaundice atypical in HF except yellow fever; test results for hepatitis antigens positive; fulminant infection resembling VHF may be seen in persons with underlying immune deficiencies
Herpes simplex or varicella-zoster	Fulminant infection with hepatitis (with or without vesicular rash); elevated transaminases and leukopenia typical; disseminated disease may be noted in otherwise healthy persons; poor response to acyclovir drugs unless recognized early
HIV/AIDS	Seroconversion syndrome or HIV/AIDS with secondary infections, especially septicemia
Measles	Rash may mimic that seen in early stages of some VHFs and may sometimes be hemorrhagic; prominence of coryza and upper respiratory symptoms in measles should help differentiate; vaccine preventable
Rubella	Rash may mimic that seen in early stages of some VHFs; usually a mild disease; vaccine preventable
Hemorrhagic or flat smallpox	Diffuse hemorrhagic or macular lesions; in contrast to the VHFs, the rash may involve the oral mucosa, palms, and soles; smallpox in the wild has been eradicated
Alphavirus infection (including chikungunya and o'nyong-nyong)	Joint pain typically a predominant feature
FUNGI	
Histoplasmosis	Pulmonary disease may mimic hantavirus pulmonary syndrome; recent entry into mines or caves

TABLE 351-3 DIFFERENTIAL DIAGNOSIS OF THE VIRAL HEMORRHAGIC FEVERS—cont'd

DISEASE	DISTINGUISHING CHARACTERISTICS AND COMMENTS
NONINFECTIOUS ETIOLOGIES	
Heat stroke	History for extreme heat exposure; absence of sweating; bleeding not typical, but DIC may occur
Idiopathic and thrombotic thrombocytopenic purpura (ITP/TTP)	Presentation usually less acute than in VHF; may have prominent neurologic symptoms in TTP; coagulation factors normal and DIC absent; often respond to corticosteroids (ITP) or plasma exchange (TTP)
Acute glaucoma	May mimic the acute ocular manifestations of Rift Valley fever
Hematologic malignant neoplasms (leukemia, lymphoma)	May resemble leukemoid reaction occasionally seen in HF with renal syndrome
Drug sensitivity or overdose	Stevens-Johnson syndrome and anticoagulant (warfarin) overdose
Industrial and agricultural chemical poisoning	Especially anticoagulants, although other symptoms of VHF absent
Hematoxic snake bite envenomation	History of snake bite

AIDS = acquired immunodeficiency syndrome; DIC = disseminated intravascular coagulopathy; HF = hemorrhagic fever; HIV = human immunodeficiency virus; PCR = polymerase chain reaction; VHF = viral hemorrhagic fever.

TABLE 351-4 INDICATED CLINICAL LABORATORY TESTS AND CHARACTERISTIC FINDINGS IN PATIENTS WITH VIRAL HEMORRHAGIC FEVER

TEST	CHARACTERISTIC FINDINGS AND COMMENTS
Leukocyte count	Early: moderate leukopenia (except for hantavirus infection, in which early leukocytosis with immunoblasts is classically noted) Later: leukocytosis with left shift; granulocytosis more suggestive of bacterial infection
Hemoglobin and hematocrit	Hemoconcentration (especially noted in hemorrhagic fever with renal syndrome and hantavirus pulmonary syndrome)
Platelet count	Mild to moderate thrombocytopenia
Electrolytes	Sodium, potassium, and acid-base perturbations, depending on fluid balance and stage of disease
BUN/creatinine	Renal failure may occur late in disease
Serum chemistries (AST, ALT, amylase, γ-glutamyltransferase, alkaline phosphatase, creatinine kinase, lactate dehydrogenase, lactate)	Usually increased, especially in severe disease; AST > ALT A lactate level >4 mmol/L (36 mg/dL) may indicate persistent hypoperfusion and sepsis. Lactate dehydrogenase is typically markedly increased in hantavirus pulmonary syndrome
Sedimentation rate	Normal or increased
Blood gas	Metabolic acidosis may be indicative of shock and hypoperfusion
Coagulation studies (PT, PTT, fibrinogen, platelets, D-dimer)	DIC common in Ebola, Marburg, Lujo virus, Crimean-Congo HF, and New World arenavirus infections
Urinalysis	Proteinuria common; hematuria may be occasionally noted. Sediment may show hyaline-granular casts and round cells with cytoplasmic inclusions
Blood culture	Useful early to exclude VHF and later to evaluate for secondary bacterial infection. Blood should be drawn before antibiotic therapy is instituted
Stool culture	Useful to exclude VHF (in favor of hemorrhagic bacillary dysentery)
Thick and thin blood smears	May aid in the diagnosis of blood parasites (malaria and trypanosomes), bacterial sepsis (meningococcus, *Capnocytophaga*, and anthrax), and ehrlichiosis. All negative in VHF unless coinfection
Rapid test, PCR, or other assay for malaria	Negative in VHF unless coinfection with malaria

ALT = alanine aminotransferase; AST = aspartate aminotransferase; BUN = blood urea nitrogen; DIC = disseminated intravascular coagulation; HF = hemorrhagic fever; PCR = polymerase chain reaction; PT = prothrombin time; PTT = partial thromboplastin time; VHF = viral hemorrhagic fever.

Oxygenation and Ventilation

In the early phases of disease and in the absence of iatrogenic pulmonary edema, most patients can be supported with oxygen administered by nasal cannula or face mask. The exception is hantavirus pulmonary syndrome, for which early endotracheal intubation and mechanical ventilation (Chapter 91) are often life-saving. In neurologically intact patients with hypoxemia, noninvasive positive-pressure ventilation may be a useful adjunct to passive oxygenation. When mechanical ventilation is required, lung-protective tidal volumes of 6 mL/kg of ideal body weight should be employed. High-volume hemofiltration[14] and extracorporeal membrane oxygenation have been used with apparent benefit in hantavirus pulmonary syndrome.

Antibiotics and Secondary Infection

Until a diagnosis of viral hemorrhagic fever can be confirmed, patients should be immediately covered with appropriate antibacterial or antiparasitic therapy, with specific consideration of malaria (Chapter 316), tick-borne rickettsial diseases (Chapter 302), and gram-negative sepsis (Chapter 94) as appropriate based on epidemiologic risk factors. Since translocation of gut bacteria to the blood stream is a concern, antimicrobial regimens should cover enteric organisms. These drugs should then be stopped when infection with a hemorrhagic fever virus is confirmed unless there is evidence of coinfection. Secondary bacterial infection should be suspected when symptoms persist or new fever appears after about 2 weeks of illness, a time when most viral hemorrhagic fevers either have resulted in death or are resolving.

Antiviral Therapy

The single monoclonal antibody MAb114 and the triple monoclonal antibody cocktail drug REGN-E83 significantly decrease mortality from acute hemorrhagic Ebola infections.[A1] However, data are available only for the Zaire species of the virus.

Ribavirin is recommended for Lassa fever, other arenavirus infections, and hemorrhagic fever with renal syndrome, but data in support of its use are limited, and this off-label use is not approved by the U.S. Food and Drug Administration (Table 351-5).[15] Results are mixed and consensus is lacking regarding ribavirin for Crimean-Congo hemorrhagic fever. In vitro data show activity against dengue, yellow fever, Rift Valley fever, and Omsk hemorrhagic fever viruses, but clinical studies have not been performed. The main side effects of intravenous ribavirin are a mild to moderate hemolytic anemia, which infrequently necessitates transfusion and disappears with cessation of treatment, and rigors when the drug is infused too rapidly.

Favipiravir, which is licensed in many countries to treat influenza, has shown efficacy in nonhuman primate models of Lassa fever but has not yet been studied in humans.[16] The Chinese drug chongcao shenkang has been reported to have benefit for hemorrhagic fever with renal syndrome.

Transfusion of appropriately titered convalescent plasma within the first 8 days of illness has been reported to reduce the case-fatality of Argentine hemorrhagic fever from 15 to 30% to less than 1%. However, this therapy has been associated with a convalescent phase neurologic syndrome characterized by fever, cerebellar signs, and cranial nerve palsies in 10% of treated patients. Animal studies show convalescent plasma to be efficacious in Lassa fever as well but only if it contains a high titer of neutralizing antibody and if there is a close antigenic match between the infecting viruses of the donor and recipient. Convalescent plasma also appears to be efficacious for Crimean-Congo hemorrhagic fever and Rift Valley fever, but no controlled data exist. A clinical trial of convalescent plasma for Ebola virus disease did not show efficacy.

TABLE 351-5 RIBAVIRIN THERAPY FOR VIRAL HEMORRHAGIC FEVER

INDICATION	ROUTE	DOSE*	INTERVAL
Treatment	IV†	30 mg/kg (maximum 2 g)	Loading dose, followed by:
	IV†	15 mg/kg (maximum 1 g)	every 6 hours for 4 days, followed by:
	IV†	7.5 mg/kg (maximum 500 mg)	every 8 hours for 6 days
Prophylaxis	PO	35 mg/kg (maximum 2.5 g)	Loading dose, followed by:
	PO	15 mg/kg (maximum 1 g)	every 8 hours for 10 days

*Pharmacokinetic and sensitivity testing for ribavirin has not been extensively performed for each viral hemorrhagic fever. The intravenous dose used is derived from that found efficacious in Lassa fever. Oral ribavirin has also been reported to be efficacious in many viral hemorrhagic fevers, especially for Crimean-Congo hemorrhagic fever, but few controlled data are available. Intravenous administration is strongly suggested whenever possible. The dose should be reduced in persons known to have a creatinine clearance of less than 50 mL/minute.

†The drug should be diluted in 150 mL of 0.9% saline and infused slowly.

IV = intravenous; PO = oral.

Various immune modulators, including ibuprofen, corticosteroids, anti–tumor necrosis factor-α, nitric oxide inhibitors, statins, and interleukins, have not shown conclusive benefit in the treatment of sepsis. In a small study, recombinant interleukin-2 reduced the degree of acute renal insufficiency in hemorrhagic fever with renal syndrome, but further studies are needed before it can be considered the standard of care. Corticosteroids (e.g., 200 mg intravenous hydrocortisone per day, divided into two to four daily doses or administered by continuous infusion) are recommended in viral hemorrhagic fevers only when adrenal insufficiency is strongly suspected, the target blood pressure is not maintained despite adequate fluid repletion and vasopressors, or cerebral edema is suspected.

Management of Pregnancy

Uterine evacuation in pregnant patients appears to lower maternal mortality and should be considered, given the extremely high maternal and fetal mortality associated with viral hemorrhagic fever.[17] However, this procedure must be performed with extreme caution because it can be considered high risk with regard to potential nosocomial transmission. Although it is technically contraindicated in pregnancy (U.S. Food and Drug Administration Category X), considering the very high maternal and fetal mortality, ribavirin should nevertheless be considered as a life-saving measure for the mother who has a viral hemorrhagic fever for which the drug is efficacious (see Tables 351-2 and 351-5). Recent experience following this approach in the management of patients with Lassa fever in Nigeria resulted in favorable outcomes.[18]

Pain Management and Other Considerations

Oral or parenteral acetaminophen, tramadol, other nonsteroidal non-opioid analgesics (see Table 26-4), or opiates (see Table 26-6) should be used as needed for pain control, adjusting as necessary for hepatic insufficiency. Use of salicylates and nonsteroidal anti-inflammatory drugs should be avoided because of the risk of bleeding. Prophylactic therapy for gastrointestinal stress ulcers with proton pump inhibitors or histamine H_2-receptor antagonists is recommended (see Table 124-1). Antiemetics, such as the phenothiazines, are frequently warranted. Seizures can usually be managed with standard medications (Chapter 372).

Discharge and Monitoring

Because the patient's clinical status and infectivity generally correlate with the level of viremia, patients who have recovered from their acute illness can safely be assumed to have cleared their viremia and can be discharged without concern of subsequent transmission, with the exception of the risk of sexual transmission (see later) and possible transmission to infants through breast milk in women infected during pregnancy. PCR testing may detect insignificant RNA for days or even weeks after clinical recovery, so discharge should not depend on a negative PCR test.

PREVENTION

Infection Prevention and Control

The patient should be placed in an isolated room with an antechamber, if possible, for gowning of health care personnel. It is prudent to place the patient in a negative airflow room if it is available, but hermetically sealed isolation chambers are not required. Insecticide-treated bed nets and room screens should be used in open-air settings to prevent transmission of arthropod-borne hemorrhagic fever viruses. Access to the patient should be limited to a small number of designated staff with specific training regarding infection prevention and control for viral hemorrhagic fevers. Although normal barrier nursing precautions to prevent parenteral and droplet exposure to blood and body fluids are usually adequate to prevent infection, specific enhanced protection measures, including personal protective equipment, are warranted if the diagnosis of viral hemorrhagic fever is suspected.[19] Other essential components of infection prevention and control include proper staff-to-patient ratios, waste disposal, and disinfection procedures. Small-particle aerosol precautions should be used when procedures such as endotracheal intubation may generate aerosols.[20]

Contact Tracing

The early nonspecific presentation of the viral hemorrhagic fevers poses a serious challenge to effective epidemiologic surveillance. Fortunately, the low secondary attack rates afford a measure of reassurance even when cases go unrecognized as long as proper barrier nursing is maintained. Furthermore, because mild cases, which may be still more difficult to recognize, are usually not very infectious, missed or delayed diagnosis of these patients is unlikely to pose a problem from an infection control standpoint.

Persons with unprotected direct contact with a patient during the symptomatic phase of a human-to-human communicable viral hemorrhagic fever should be monitored daily for evidence of disease for the duration of the longest possible incubation period, starting after their last contact (see Table 351-2). Given the generally low secondary attack rates, especially outside of caretakers, widespread contact tracing, laboratory testing, and postexposure prophylaxis are not indicated for casual contacts. Close contacts should check their temperature daily and record the results. Despite lack of evidence for transmission during the incubation period, it is usually recommended that exposed persons avoid intimate contact with household members that might result in exposure to body fluids, such as sex, kissing, and sharing of utensils, for the duration of the incubation period. Confinement of asymptomatic persons is not warranted, but persons who develop fever or other signs and symptoms suggestive of viral hemorrhagic fever should be immediately isolated until the diagnosis can be ruled out.

Vaccines

Vaccines for viral hemorrhagic fevers are at various stages of development. The 17D live attenuated yellow fever vaccine has a generally excellent protection and safety profile despite recognition of rare serious adverse events in elderly persons. In resource-limited settings, one-fifth of the standard dose appears to be equally effective.[A2] Confirmed previous vaccination with 17D should essentially exclude the diagnosis of yellow fever unless the patient was immunocompromised at the time of vaccination.

Two vaccines have recently received regulatory approval for infection by Zaire ebolavirus. The single dose recombinant vesicular stomatitis virus–Zaire Ebola virus vaccine (rVSV-ZEBOV) has high protective efficacy and has been used extensively in recent outbreaks to vaccinate exposed health care workers, close contacts of patients, and close contacts of the close contacts themselves.[A3] Adverse effects are frequent but mostly minor, but vaccine-induced arthritis, dermatitis, and vasculitis have been reported.[A4] Ad26.ZEBOV, MVA-BN-Filo, which is a heterologous two-dose vaccine given 56 days apart with minimal adverse effects, is principally designed for primary prevention.[21] Strategies on how both vaccines should be used for optimal effect are still being debated.[22] The duration of protection, the risks of breakthrough infections, and any need for boosters remains unknown.[23] Research is underway on vaccines that would confer protection against other ebolaviruses.[24]

The live attenuated vaccine Candid 1 is highly protective against Argentine hemorrhagic fever, but it is licensed only in Argentina. Candid 1 may also be effective in Bolivian hemorrhagic fever, but it does not appear to protect against other arenavirus infections.

A tetravalent vaccine for dengue virus infection unfortunately enhances the risk of severe disease in patients who have not been previously infected.[A5] The vaccine is now recommended only for children who have previously had dengue fever or for populations in which most people have been previously infected.[25] Experimental vaccines for hantavirus,[26] Crimean-Congo

hemorrhagic fever,[27] Lassa fever,[28] Marburg virus disease,[29] Rift Valley fever, Omsk hemorrhagic fever, and Kyasanur Forest disease may be efficacious, but most have not been widely tested and are not widely approved or available.

Postexposure Prophylaxis

Postexposure prophylaxis should be considered only in persons with distinct high-risk exposure, defined as follows: (1) penetration of skin by a contaminated sharp instrument (e.g., needlestick injury), (2) exposure of mucous membranes or broken skin to blood or body secretions (e.g., blood splashing in the eyes or mouth), (3) participation in emergency procedures without appropriate personal protective equipment (e.g., resuscitation after cardiac arrest, intubation, or suctioning), (4) prolonged (i.e., hours) and continuous contact in an enclosed space without appropriate personal protective equipment, and (5) unprotected sex with a male who recovered from a viral hemorrhagic fever in the prior 18 months, unless his semen has been tested and confirmed negative. The most infectious patients are those with severe clinical conditions, usually late in the course of illness. Prophylaxis should not be used when the only exposure was during the incubation period or after acute disease has subsided.

Although no data exist, it is reasonable to use the newly approved monoclonal antibody treatments for to Ebola virus disease as postexposure prophylaxis when a high-risk exposure occurs in an unvaccinated person.[30] Postexposure prophylaxis with oral ribavirin has been recommended for Lassa fever, other arenavirus infections, and Crimean-Congo hemorrhagic fever, although no systematic data are available on its efficacy, and the frequent minor adverse events sometimes can be mistaken for the early signs of disease. When used, oral ribavirin should be started immediately after the exposure but not before counseling between the patient and the physician. The drug should be taken with food. Baseline hemoglobin, hematocrit, bilirubin, and creatinine levels should be determined, and therapy should be adjusted or reconsidered if significant anemia or renal insufficiency develops.

Convalescent plasma is given as postexposure prophylaxis for Argentine hemorrhagic fever. Numerous experimental vaccines, monoclonal antibodies, and other compounds have shown efficacy as postexposure prophylaxis in animal models, but reliable data on their efficacy in humans are not available.

Reservoir and Vector Control

Avoiding contact with bats, primarily by avoiding entry into caves and mines in endemic areas, is a key prevention measure for Ebola and Marburg viruses. Personal protective equipment may be indicated for miners and other persons who work in these environments. Humans should also avoid exposure to fresh blood, body fluids, or meat of wild animals, especially nonhuman primates.

For rodent-borne viruses, whose reservoirs often colonize human dwellings, improved "village hygiene" is recommended, such as eliminating unprotected storage of garbage and foodstuffs and plugging holes that allow rodents to enter homes. Prevention of the mosquito-borne hemorrhagic fever viruses hinges on controlling *Aedes* mosquitoes in and around the home, primarily by elimination of clean standing water containers that serve as larval habitats and use of screened windows and doors, insecticide-treated bed nets, protective clothing, mosquito repellent, and aerosol bomb insecticides in enclosed spaces. Analogous measures can help protect against tick bites.

PROGNOSIS

Mild and asymptomatic cases of even the most virulent viral hemorrhagic fevers have a benign outcome. More severe viral hemorrhagic fevers typically evolve rapidly. In fatal cases, death usually occurs within 7 to 10 days after the onset of symptoms in filovirus infection and in about 2 weeks with arenaviruses and some of the other viruses. Death usually results not from exsanguination but rather from a process akin to septic shock (Chapter 94) when insufficient effective circulating intravascular volume leads to hypotension, cellular dysfunction, acute kidney and hepatic injury, respiratory failure, and metabolic and electrolyte derangements, often in the setting of systemic inflammation and cytokine abnormalities. Less commonly, meningoencephalitis, pancreatitis, rhabdomyolysis, and cardiac arrhythmias lead to a fatal outcome. Thrombotic coronary or cerebrovascular accidents related to thrombocytosis and a hypercoagulable state have been documented during early recovery after Ebola virus disease.

Common indicators of a poor prognosis include very young or old age, hemodynamic instability and shock, bleeding, neurologic manifestations, high levels of viremia (or surrogate measurements of antigen or genome copies), neutrophilia, elevated liver enzymes and serum creatinine levels,[31] and pregnancy, especially during the third trimester, during which maternal and fetal mortality may be above 90%. Elevated levels of the biomarkers plasminogen activator inhibitor-1 and soluble thrombomodulin portend a worse prognosis in Lassa fever.[32]

Modern supportive critical care has been associated with a substantial reduction in the mortality rate for Marburg and Ebola virus disease. Whether those benefits relate to the uncontrolled use of experimental therapies, better intensive care, genetic predisposition, or fewer comorbid conditions is unknown.

Sequelae

For Ebola virus disease, convalescence can be prolonged, often with a year or more of persistent arthralgia, ocular complications (including potentially sight-threatening uveitis that may result in early cataract formation), neurologic syndromes,[33] abdominal pain, extreme fatigue, anorexia, and mental health sequelae.[34] Ebola virus can persist for months or even years in immunologically protected tissue compartments, chambers of the eye, central nervous system, and in the fetus, placenta, and amniotic sac/fluid of women infected during pregnancy. Ebola virus RNA also has been detected in the semen over a year after acute disease, with evidence of rare male-to-female sexual transmission as long as 15 months after recovery. Remdesivir may reduce the presence of Ebola virus RNA in the semen of survivors,[35] but abstinence or safe sex with condoms is recommended for at least 1 year after recovery or until virus clearance from the semen can be confirmed by laboratory testing. Ebola virus RNA has been detected in the breast milk of survivors during both acute illness and convalescence, including in one case 500 days after recovery. Furthermore, Ebola virus RNA has been found in the breast milk of some lactating women in whom acute disease was never recognized.

Ebola virus can persist and rarely be associated with organ-specific inflammatory syndromes and recrudescent disease. In one example, detectable Ebola virus RNA in the blood of a previously vaccinated survivor at 6 months after recovery led to 91 secondary cases. Ebola virus has rarely been isolated from the anterior chamber fluid of the eye (associated with panuveitis) and from the cerebrospinal fluid (associated with meningoencephalitis) months after the onset of disease; such patients eventually cleared the virus and recovered, but secondary transmission can occur.

Lassa virus can persist in the semen of survivors.[36] Hearing loss, which may be permanent, is a common sequela in of survivors of Lassa fever[37] and has also been reported after Venezuelan hemorrhagic fever. It first appears during convalescence, may be unilateral or bilateral, and is not associated with severity of the acute disease or treatment with ribavirin. Optic retinopathy with vision loss has been noted in survivors of Rift Valley fever.

Management of the sequelae of viral hemorrhagic fever is generally supportive, with the exception of uveitis, for which urgent treatment with topical steroids and atropine may be sight-saving. Breast-feeding should be avoided during convalescence unless there is no other way to support the baby. Proper infection prevention and control precautions should be taken when attending all births to women who were infected with filoviruses during pregnancy.

352 ARBOVIRUSES CAUSING FEVER, RASH, AND NEUROLOGIC SYNDROMES

J. DAVID BECKHAM

COMMON FEATURES OF ARBOVIRUSES

DEFINITION

Zoonotic viruses (Chapter 303) in animal populations infect humans. An extremely large reservoir of known and unknown viruses represents important causes of described and emerging human infectious diseases. Modes of transmission include human contact with animal bodily fluids or excrement, bite wounds, and direct exposure to an animal carcass. However, many arthropods have evolved to utilize animal blood as a food source, and viruses have exploited this adaptation as a reliable method of transmission. Infectious viruses that are transmitted through arthropod vectors are termed arthropod-borne viruses (arboviruses).

PATHOBIOLOGY

Vector Transmission Cycles

Arboviruses are transmitted to humans most commonly from the bite of a mosquito or tick species. However, other vectors include sand flies (*Phlebotomus* spp) and biting midges (*Culicoides* spp). Arboviruses infect new vectors most commonly by feeding on an intermediate host, such as small rodents, avian species, or nonhuman primates. The animal host acts as an amplifying host for the virus and can transmit to uninfected vectors. Transovarial transmission from a female to eggs and cofeeding between infected and uninfected insect vectors can contribute to the population of infectious vectors. Many arboviruses also cause persistent infection in the vector, thereby allowing for survival over the winter and transmission over multiple seasons. In general, arboviruses often exist in an enzootic (animal) or sylvatic (jungle-based) cycle of transmission between the vector and an animal host. At times, the vectors may feed on a susceptible population, such as domestic animals (epizootic cycle), or feed on humans to cause an urban cycle or epidemic. If the amount of virus in the blood of infected domestic animals or humans is not high enough or sustained enough over time to support transmission to uninfected vectors, then the host acts as a dead-end or incidental host for the virus. The endemic cycle of an arbovirus between invertebrate and vertebrate hosts determines the geographic range and epidemiology of exposure for humans. As human populations continue to expand into new regions, sylvatic arboviruses that have not yet been identified will have opportunities to develop new epidemic cycles in human populations. Thus, arboviruses represent an important source of future emerging infectious diseases in human populations.

Phylogeny of Arboviruses

Arboviruses are RNA viruses that are largely grouped into three families of viruses (*Flaviviridae, Togaviridae*, and *Reoviridae)* and one virus order (Bunyavirales).

Flaviviridae

The *Flaviviridae* are icosahedral, enveloped viruses about 50 nm in diameter with 180 membrane and 180 envelope proteins arranged in antiparallel dimers on the surface of the viral particle. The capsid protein encloses a positive-sense, single-stranded RNA genome (about 11 kb) with a single open reading frame that has an upstream 5′ untranslated region, a 5′ m7GpppRNA cap structure, and a 3′ untranslated region with conserved RNA structure and no poly-A tail. Within the *Flaviviridae* family, the genus *Flavivirus* is divided into mosquito-borne, tick-borne, arthropod-specific, and unknown vector groups. The flaviviruses circulate between mosquito and tick species and specific mammalian hosts that include avian species, small mammals, nonhuman primates, and humans.

Togaviridae

The *Togaviridae* are lipid-enveloped viruses about 60 to 70 nm in diameter with a 5′ capped positive-sense RNA genome that is 11 to 12 kb in length with a poly-A tail. The nonstructural proteins are expressed from the first open reading frame, and a subgenomic promoter drives expression of the structural genes. The enveloped virus particle consists of E1 and E2 glycoproteins as heterodimers that then form trimers to make 80 spikes. The *Alphavirus* genus makes up many of the medically important arboviruses. All *Togaviridae* are transmitted by mosquito vectors, and individual viruses are generally divided into New World and Old World alphaviruses.

Reoviridae

Reoviridae, which include Colorado tick fever virus, are nonenveloped, double-stranded RNA viruses with a segmented genome. Colorado tick fever virus genome is relatively large (~29 kb) compared with other arboviruses and has an icosahedral capsid structure about 80 nm in diameter.

Bunyavirales

The Bunyavirales order consists of 9 viral families and 13 genera. The arboviruses of human significance are largely represented by the *Orthobunyavirus*, *Phlebovirus*, and *Orthonairovirus* genera. In general, the bunyaviruses are characterized by a spherical, enveloped virus particle that is about 80 to 120 nm in diameter and is decorated with two surface glycoproteins (Gc and Gn). The negative-sense or ambisense RNA genome is divided into three segments (L, M, and S). The L segment encodes the RNA-dependent RNA polymerase, the M segment encodes the viral glycoprotein precursors, and the S segment encodes the nucleocapsid proteins.

Infectious Process

Arboviruses are generally found in the salivary glands of the associated vector, where they arrive following replication in the midgut after a blood meal from an infected, amplifying host. In some cases, an invertebrate vector can also become infected from transovarial transmission, in which the female vector transmits virus to eggs, or by cofeeding when an infected vector feeds on a previously uninfected host at the same time as an uninfected vector. Once an infected vector bites a mammalian or avian host, the salivary gland excretion, which precedes feeding, allows the arbovirus to be distributed into the subcutaneous tissue of the host. The virus replicates locally in the dermal tissue, epithelial cells, endothelial cells, or local tissue-resident immune cells such as dendritic cells. Local replication results in viral spread to draining lymph nodes, which are the site of primary viral replication, and subsequent viremia that spreads the virus to target organs, including the spleen and liver. Spread to the spleen or liver can initiate a secondary viremia that can infect the central nervous system, the placenta, or joint tissues.

CLINICAL MANIFESTATIONS

Arboviruses vary in the rate that they cause disease in humans based on many factors, including age, immune status, comorbid conditions, and prior exposure history. Exposure to an arbovirus can result in a wide range of clinical outcomes, from asymptomatic infection to severe disease. Arboviruses can cause characteristic syndromes broadly defined as a fever/rash/myalgia syndrome or a meningitis encephalitis syndrome. Fever and rash in a returning traveler (Chapter 265) from an endemic area should raise suspicion for an arboviral infection.[1] Some arbovirus members that cause fever and myalgia can also cause hemorrhagic fever syndromes (Chapter 351; Table 352-1). Other arboviruses predominantly cause infections of the central nervous system (Table 352-2) but can also cause rashes.

For individuals that develop symptoms, the initial presenting symptoms can be protean, including fever, chills, myalgias, arthralgias, and neurologic symptoms. The only differentiating features may be the geography and surrounding epidemiology of the exposure. Even in a specific region, however, clinical presentations may overlap. For example, Chikungunya virus, dengue virus, and Zika virus can co-circulate using the same vector, or coinfections may occur from *Aedes agyepti* mosquitos infected with more than one pathogen.

DIAGNOSIS

Reverse transcription polymerase chain reaction (RT-PCR) is the preferred diagnostic test when patients have viremia or active virus in the cerebrospinal fluid (CSF). Since the onset of symptoms for most patients follows clearance of active viremia, however, most patients will require virus-specific serologic testing for the presence of IgM or IgG antibodies, often with acute and convalescent titers to distinguish new infection from prior infection.[2] Many of the serologic tests used to diagnose arboviruses cross-react with co-circulating arboviruses, thereby making definitive diagnosis clinically challenging in some regions. For definitive diagnosis, virus-specific neutralizing antibody titer assays, often available through government laboratories, can help distinguish among individual arboviruses.

ABSTRACT

Arthropod-borne virus (arbovirus) infections cause a wide array of both endemic and epidemic human diseases throughout the world. With global climate change, the transmitting arthropods are rapidly expanding their geographic range. In general, arboviruses cause two predominant syndromes: fever with arthralgia/arthritis or predominantly neurologic symptoms. Some arboviruses that cause fever and arthralgia can also progress to produce hemorrhagic disease. The majority of arbovirus infections are caused by members of one of three families of viruses (*Flaviviridae, Togaviridae*, and *Reoviridae*) and one virus order (Bunyavirales). Recognition of the clinical syndrome, epidemiology, and diagnosis is essential to care for patients with potential arbovirus infections.

TABLE 352-1 ARBOVIRUS INFECTIONS CAUSING ARTHRALGIA AND MYALGIA SYNDROMES

VIRUS	TRANSMISSION CYCLE	GEOGRAPHIC DISTRIBUTION	CLINICAL SYNDROME	TREATMENT AND PREVENTION
TROPIC/SUBTROPICAL GLOBAL DISTRIBUTION				
Dengue *(Flaviviridae)*	Vector: *Aedes aegypti* Host: primates/humans	Global tropical distribution	Fever, headache, fatigue, myalgia, arthralgia, weakness	Vaccine
Chikungunya *(Togaviridae)*	Vector: *Aedes aegypti* Host: primates/humans	Global tropical distribution	Fever, myalgias, rash, arthralgias, arthritis, tenosynovitis	None
Zika *(Flaviviridae)*	Vector: *Aedes aegypti* Host: primates/humans	Global tropical distribution	Fever, chills, myalgias, rash, conjunctivitis	None
Yellow fever *(Flaviviridae)*	Vector: *Aedes* spp. Host: primates/humans	South America/Africa	Fever, chills, headache, nausea, vomiting, abdominal pain, jaundice	Vaccine
NORTH AMERICA				
Heartland *(Bunyavirales)*	Vector: *Amblyomma americanium* Host: unknown reservoir	Midwestern and Southern United States	Fever, headache, fatigue, myalgia, arthralgia, weakness	None
CENTRAL AND SOUTH AMERICA				
Mayaro *(Togaviridae)*	Vector: *Haemagogus* spp. Host: nonhuman primates	Central and South America	Fever, chills, headache, arthralgias, myocarditis	None
Tropical fever (Oropouche virus, *Bunyavirales*)	Vector: *Culicoides paranensis* biting midge Host: sloths, nonhuman primates	Central and South America	Mild febrile illness, myalgias, malaise; rare hemorrhagic disease	None
Bussuquara *(Flaviviridae)*	Vector: *Culex melanoconion* Host: small rodents	Central and South America	Fever, arthralgias	None
AFRICA				
O'nyong-nyong *(Togaviridae)*	Vector: *Anopheles* spp. Host: unknown host	Sub-Saharan Africa	Fever, headache, rash, conjunctivitis, large joint arthralgia, arthritis	None
Rift valley fever *(Bunyavirales)*	Vector: *Aedes* spp. and *Culex* spp. Host: wild ungulates and domesticated livestock	Sub-Saharan Africa	Fever, headache, myalgias, and severe disease with hepatitis and jaundice, hemorrhage	Vaccines for livestock to prevent epizootic outbreaks
EUROPE				
Sinbis *(Togaviridae)*	Vector: *Aedes* spp., *Culex* spp., and *Culiseta* spp. Host: bird species	Northern Europe, also in Russia, central Africa, Australia	Fever, macular rash, arthralgia of hands and small joints	None
Phlebotomus fever *(Bunyavirales)*	Vector: *Phlebotomus* spp. sandfly Host: unknown	Mediterranean area, western Europe, Turkey, Middle East, western India, Pakistan	Fever, rash, headache, photophobia, myalgia, arthralgia	None
ASIA				
Severe fever with thrombocytopenia syndrome virus *(Bunyavirales)*	Vector: *Haemaphysalis longicornis* tick Host: avian and small mammal species	Central and eastern Asia	Fever, myalgias, headache, arthralgia; can progress to bleeding diathesis	None
Crimean-Congo hemorrhagic fever *(Bunyavirales)*	Vector: *Hyalomma* spp. ticks Host: birds, small and large mammals	Asia, Africa, Middle East	Febrile illness, myalgia, vomiting and diarrhea; some progress to severe hemorrhagic disease	None
Omsk hemorrhagic fever *(Flaviviridae)*	Vector: *Dermacentor* spp. ticks Host: small mammals	Omsk, Kurgan and regions of western Siberia	Fever, headache, chills, vomiting, myalgia, photophobia, conjunctival suffusion; fatality rate < 3%	Tick-borne encephalitis vaccine may provide cross-protection
AUSTRALIA				
Ross River *(Togaviridae)*	Vector: *Aedes* spp. and multiple mosquito vectors Host: marsupials	Australia	Fever, rash, arthralgias, arthritis, myalgias	None
Edge Hill *(Flaviviridae)*	Vector: *Aedes* spp. and *Culex* spp. Host: marsupials	Australia	Fever and proximal joint arthritis	None

TABLE 352-2 ARBOVIRUS INFECTIONS CAUSING NEUROLOGIC SYNDROMES

VIRUS	TRANSMISSION	GEOGRAPHIC DISTRIBUTION	CLINICAL SYNDROME	TREATMENT AND PREVENTION
NORTH AMERICA				
West Nile *(Flaviviridae)*	Vector: *Culex* spp. mosquitoes Host: passerine birds	North America, South America, Africa, Europe, Middle East, Asia, Australia	Fever, myalgias, rash, nausea, vomiting, diarrhea, meningitis, paralysis, encephalitis	None
Powassan *(Flaviviridae)*	Vector: *Ixodes* spp. ticks Host: small mammals and white-tailed deer	North America	Fever, malaise, myalgia, nausea, rash, meningitis, encephalitis	None
Eastern equine encephalitis *(Togaviridae)*	Vector: *Culiseta melanura* mosquito Host: bird species	East coast and upper Midwest United States	Fever, chills, malaise, myalgias, arthralgias, meningitis, encephalitis	None
St. Louis encephalitis *(Flaviviridae)*	Vector: *Culex* spp. Host: avian species	Continental United States	Fever and myalgias, meningitis, encephalitis	None
Western equine encephalitis *(Togaviridae)*	Vector: *Culex tarsalis* mosquitoes Host: avian species	North America, rare cases	Fever, myalgias, meningitis, encephalitis	None
California encephalitis group *(Bunyavirales)*	Vector: *Aedes* spp. mosquitoes Host: small mammals	North America	Fever, chills, nausea, vomiting, myalgias, seizures, encephalitis	None
Colorado tick fever *(Reoviridae)*	Vector: *Dermacentor andersoni* tick Host: small mammals and rodents	North America, mountain west	Biphasic fever, chills, headache, myalgias, abdominal pain, rash, meningitis	None
CENTRAL AND SOUTH AMERICA				
Venezuelan equine encephalitis *(Togaviridae)*	Vector: *Culex, Aedes, Mansonia, Psorophora* spp. mosquitoes Host: rodents/small mammals	Central and South America	Fever, malaise, chills, myalgia, headache, encephalitis ataxia, seizures, paralysis	No licensed vaccine
Rocio *(Flaviviridae)*	Vector: *Psorophora* spp. mosquitoes Host: birds	Brazil and South America	Fever, headache, malaise, conjunctivitis; 30% of cases develop meningitis, encephalitis; 10% mortality	None
AFRICA				
Usutu *(Flaviviridae)*	Vector: *Culex pipiens* mosquitoes Host: avian species	Africa and Europe	Fever and myalgias, meningitis, encephalitis	None
EUROPE				
Tick-borne encephalitis *(Flaviviridae)*	Vector: *Ixodes* spp. ticks Host: mammals, livestock	Eastern Europe and northern Asia	Fever, myalgias, meningitis, encephalitis, poliomyelitis	Four vaccines available in endemic regions
Louping ill *(Flaviviridae)*	Vector: *Ixodes* spp. ticks Host: small rodents	Europe and Asia	Fever, myalgias, fatigue, meningitis, encephalitis	None
Toscana *(Bunyavirales)*	Vector: *Phlebotomus* spp. sandfly Host: unknown reservoir	Mediterranean Europe	Fever, headache, myalgias, meningitis, encephalitis	None
ASIA				
Japanese encephalitis *(Flaviviridae)*	Vector: *Culex tritaeniorhychnus* Host: aquatic birds and pigs	Southeast Asia, India, western Pacific Islands, northern Australia	Fever, headache, nausea, vomiting, meningitis, encephalitis	Live-attenuated vaccine
AUSTRALIA				
Murray Valley encephalitis *(Flaviviridae)*	Vector: *Culex* spp. mosquitoes Host: small mammals and marsupials	Northern Australia, New Guinea	Fever, chills, myalgias, rash, meningitis, encephalitis	None

spp = species.

TREATMENT AND PREVENTION

Specific antiviral therapeutic options are rarely available for acutely ill patients. In general, prevention is based on limiting exposure to vectors. Vaccines are available for yellow fever, dengue, tick-borne encephalitis virus, and Japanese encephalitis viruses. In endemic regions, individual prevention measures include DEET-containing repellants, permethrin-embedded clothing, long pants/sleeves, and bed nets. Vector control methods include drainage or removal of stagnant water sources where vectors reproduce.

FEVER AND MYALGIA SYNDROME

FLAVIVIRIDAE

YELLOW FEVER

DEFINITION AND EPIDEMIOLOGY

Yellow fever virus is a mosquito-borne member of the *Flaviviridae* family with characteristic, small, spherical, enveloped particles with three structural proteins that contain a positive-sense, single-stranded RNA genome. The genus, *Flavivirus* (flavi = yellow), acquired its name from the characteristic jaundice associated with yellow fever infection.

Yellow fever virus continues to cause major epidemics in tropical and subtropical regions of Africa and South America despite a safe and effective vaccine. Recent estimates report 63,000 to 158,000 severe annual infections in Africa, resulting in 29,000 to 75,000 deaths per year.[3] In South America, severe infections are estimated to be 4000 to 15,000 per year and deaths to be 2000 to 7000 per year. Yellow fever virus exhibits a sylvatic and urban transmission cycle between nonhuman primates and humans, respectively, with the *Haemagogus* spp and *Aedes aegypti* mosquitoes. Large outbreaks in densely populated urban areas are likely spillover infections from sylvatic outbreaks where large populations of *A. aegypti* mosquitoes breed in urban environments. The magnitude and duration of yellow fever viremia are sufficient to infect naïve, uninfected *A. aegypti* mosquitoes, thereby resulting in amplification of yellow fever in urban cycles of transmission.

PATHOBIOLOGY

Following a bite from a yellow fever virus–infected mosquito, the virus replicates in the dermal tissue epithelial cells and resident dendritic cells prior to spreading to a local draining lymph node. Following viral replication in the innate immune cells of the draining lymph node, yellow fever virus spreads to the liver, spleen, heart, and kidneys. Infection of Kupffer cells and hepatocytes in the liver results in liver inflammation and injury and can often cause significant liver dysfunction.

CLINICAL MANIFESTATIONS

The majority of individuals infected with yellow fever virus remain asymptomatic or mildly symptomatic. In others, however, a 3- to 6-day incubation period precedes acute yellow fever, which is characterized by the sudden onset of fever, chills, headache, myalgias, fatigue, weakness, nausea, and vomiting. Symptoms usually resolve within 1 week, but fatigue and weakness may persist. Virus is typically detectable in the serum for the first week of symptoms and clears as symptoms resolve. After a brief remission, about 12% of infected patients develop severe disease characterized by the return of fever, abdominal pain, nausea, vomiting, jaundice, and oliguria. The liver disease results in elevated levels of bilirubin and aminotransferases, with decreased hepatic synthesis of clotting factors. Some patients develop hemorrhagic manifestations of diffuse intravascular coagulation (Chapter 161), which is characterized by ecchymoses as well as bleeding from mucosal surfaces and needle puncture sites. Associated acute renal failure and hemorrhagic shock (Chapter 92) can occur.

DIAGNOSIS

The differential diagnosis is broad and includes acute viral hepatitis (Chapter 134), other arboviruses (Chapter 351), and malaria (Chapter 316). Since virus is detectable in human serum during the first 7 to 10 days following the onset of symptoms, yellow fever virus nucleic acid testing using an RT-PCR test may provide a diagnosis prior to serology. Since patients usually present later in the course of disease, laboratory diagnosis of yellow fever is generally accomplished by testing serum for virus-specific IgM antibodies and neutralizing antibodies. An elevated antibody level is diagnostic in unvaccinated patients, but a single antibody test cannot differentiate between the vaccine and natural infection, so serial serology showing a greater than four-fold increase in anti–yellow fever virus IgM or IgG between acute-phase and convalescent-phase samples is required for diagnosis in vaccinated persons.[4] Antibodies to one flavivirus can cross-react with other circulating flaviviruses, such as dengue virus, so confirmatory testing for neutralizing antibodies using plaque-reduction neutralization titers may be needed.

TREATMENT, PREVENTION, AND PROGNOSIS

Therapeutic options include supportive care with fluid resuscitation, critical care management, and renal replacement therapy when indicated (Chapter 351). Live-attenuated vaccine produces robust, long-lived neutralizing antibody and cellular immune responses,[A1] with a single lifetime dose recommended for travelers to endemic regions. Severe adverse events occur at a rate of <1 case per 100,000 doses. For severe yellow fever, the case-fatality rate is about 50% in unvaccinated individuals.

DENGUE VIRUS

DEFINITION AND EPIDEMIOLOGY

Dengue virus, which is a member of the *Flaviviridae* family (genus *Flavivirus*), causes infection by one of four serotypes. As with other flaviviruses, the lipid envelope is decorated with viral structural proteins, but its envelope protein varies by as much as 30 to 40% among the different serotypes. This large divergence is the basis for cross-reactive antibody reactions that are non-neutralizing but potentially enhance the severity of the clinical manifestations.

Dengue virus causes an estimated 390 million cases each year and continues to expand into the tropics and subtropics across the world (E-Fig. 352-1), where about 40% of the global population is at risk. Dengue virus circulates in urban cycles largely owing to the success of *A. aegypti*, its principal vector, to spread and reproduce among human dwellings in small containers of fresh water found in discarded tires, containers, jars, and other vessels. *Aedes albopictus* can also act as a vector.

PATHOBIOLOGY

All four serotypes of dengue virus cause dengue fever, and more severe dengue is typically associated with dengue virus 2 infection. The risk for developing severe dengue significantly increases in individuals who have preexisting immunity to a dengue virus serotype and then develop an acute infection with a different dengue virus serotype.[5] The mechanism, which is referred to as antibody-mediated enhancement, occurs when poorly neutralizing or low titer cross-reacting antibodies from the first dengue virus infection are enhanced by a second dengue virus infection from a different serotype or following infection with Zika virus, which is closely related to dengue virus. Human autopsy studies following severe dengue virus infection show antigen and nucleic acid in the cells of the skin, liver, spleen, lymph nodes, kidney, lung, thymus, and brain.

CLINICAL MANIFESTATIONS

Following an incubation period of 2 to 7 days, patients can exhibit asymptomatic infection (40 to 80%) or dengue fever,[6] which is characterized by sudden onset of high fever (40° C/104° F) accompanied by two or more of the following symptoms during the febrile phase: severe headache, retroorbital pain, myalgias/arthralgias, nausea, vomiting, adenopathy, and macular rash. Petechiae and epistaxis may also be present. The initial illness persists for about 7 days, whereas viremia persists for approximately 4 to 5 days, thereby allowing for transmission from humans to mosquitoes during the typical febrile period of disease. Following the initial febrile phase, most patients defervesce and begin to recover, but 1 to 5% of patients develop severe dengue, which is characterized by plasma leakage, shock, coagulation derangement, and end-organ disease resulting in hepatitis, encephalopathy, myocarditis, or severe bleeding (Chapter 351). Warning signs for severe dengue include abdominal pain, persistent vomiting, fluid accumulation, mucosal bleeding, lethargy, and liver enlargement >2 cm.

DIAGNOSIS

Laboratory testing may reveal thrombocytopenia, leukopenia, and mildly elevated liver aminotransferase levels. As patients defervesce, an increasing hematocrit, in part due to plasma leakage, and a rapid decrease in platelet count can indicate risk for development of severe dengue.

The diagnosis is best made during acute infection by RT-PCR for dengue virus nucleic acid in serum, alone or in combination with antigen testing for dengue nonstructural protein 1 by immunoassay. After about 4 days following the onset of fever, the most useful test is an IgM enzyme-linked immunoassay (ELISA), and a single serum sample strongly suggests recent dengue virus infection in regions where cross-reactive flaviviruses are not likely (E-Fig. 352-2). Plaque reduction neutralization antibody titers can be used to verify a positive dengue IgM antibody test result. The presence of IgG is indicative of past infection and not necessarily current infection. Moreover, cross-reactivity between antibodies to the individual dengue virus serotypes, other circulating flavivirus infections, or vaccines such as yellow fever virus vaccine may provide false-positive serology results.

TREATMENT, PREVENTION, AND PROGNOSIS

No specific therapy is effective for dengue virus. Ivermectin can accelerate the clearance of viral protein but has not been shown to be of clinical benefit.[A2] Supportive care includes fever reduction with acetaminophen while avoiding nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen and aspirin, which can potentiate the risk for bleeding. For patients diagnosed with dengue with warning signs or severe dengue, hospitalization and close monitoring may be required with supportive care, including fluid resuscitation with infusion of crystalloid solutions and oxygen administration.

Vaccination against dengue has shown promising results.[7,8] A quadrivalent dengue virus vaccine has an 80% efficacy against infection in children ages 4 to 16 years and provides 90% protection against hospitalization.[A3,A4] Infecting *A. aegypti* mosquitoes with *Wolbachia pipientis* makes them less susceptible to dengue virus and can provide about a 75% reduction in dengue infection in endemic areas.[A5]

Severe dengue has a case-fatality rate that ranges from <1 to 5%. Appropriate supportive care in a center with experience treating severe dengue reduces overall mortality to close to 1%.

ZIKA VIRUS

DEFINITION AND EPIDEMIOLOGY

Zika virus is a mosquito-borne flavivirus that is closely related to dengue virus. Previously confined to Africa and Southeast Asia, Zika virus emerged in 2008 to cause large outbreaks of febrile disease with myalgias in adults in tropical and subtropical regions throughout the world. During the global outbreak, newly described Zika virus complications included postinfectious Guillain-Barré syndrome, sexual transmission, and vertical transmission of Zika virus in pregnant women, and congenital Zika virus syndrome became appreciated.

Zika virus, which was first recognized in a febrile macaque and *Aedes africanus* mosquitoes at the edge of the Zika forest in Uganda, is now an important cause of human disease throughout the world.[9] Two distinct lineages have been identified in Africa and Asia. In 2007, a large outbreak of Zika virus on Yap Island was followed by outbreaks across the Pacific Ocean and subsequently in Brazil, other countries in South America, and Central America. By 2019, 87 countries reported Zika cases. Zika is a cause of Guillain-Barré syndrome (Chapter 388), and infection of pregnant females results in significantly increased risk of fetal abnormalities, including microcephaly (termed congenital Zika syndrome). The largest recorded outbreak was a reported 2,751 cases in Brazil between 2015 and 2016, though this number is likely an undercount.[10]

PATHOBIOLOGY

Zika virus is spread principally by *A. aegypti* mosquitoes, although *A. albopictus* can also be a potential vector. The virus replicates in the dermal tissue and subsequently spreads to draining lymph nodes and the reticuloendothelial system, where it precipitates a prolonged viremia that can persist for 7 to 10 days and spread infection to end organs. The viremia can result in transmission to an uninfected mosquito that is feeding on a viremic individual in regions where competent mosquito vectors and susceptible individuals coexist. Infectious virions and viral RNA can be found in genital secretions, and sexual transmission occurs especially in nonendemic regions. In pregnant women, the virus can infect the placenta and the fetus, thereby causing placental inflammation, injury, and insufficiency, with increasingly severe fetal outcomes associated with infection earlier in pregnancy. During fetal infection, Zika virus can infect epithelial cells, thereby resulting in diffuse congenital malformations, but it also infects astrocytes and neuroprogenitor cells in fetal brain tissue, thereby resulting in developmental defects in the central nervous system and microcephaly. A significant number of infants also develop ocular disease characterized by retinal and choroid disease that results in long-term visual disturbances and blindness.

CLINICAL MANIFESTATIONS

In adults, Zika virus is asymptomatic in about 80% of cases. In symptomatic Zika virus infection, which follows an incubation period of about 7 days, patients develop a mild febrile syndrome characterized by fever, myalgias, arthralgias, a maculopapular rash, and conjunctivitis. In pregnant women, 20% of fetuses develop the severe neurologic abnormalities of congenital Zika syndrome.[11]

DIAGNOSIS

The diagnosis is suggested by the acute clinical symptoms and is made by a positive Zika virus nucleic acid amplification testing of serum or urine. Patients generally should be tested for dengue virus IgM antibody as well because of the overlap in symptoms and epidemiology.[12] If a symptomatic pregnant woman is diagnosed with acute Zika virus infection, prenatal ultrasound is often recommended.[13] If amniocentesis is completed as part of clinical care, amniotic fluid should be analyzed for Zika virus nucleic acid amplification testing.

TREATMENT, PREVENTION, AND PROGNOSIS

No approved therapy or vaccine is currently available for Zika virus, although a candidate has been shown to be safe and to produce durable immune responses.[A6] In immunocompetent adults, symptoms almost always resolve in 7 to 10 days without significant long-term complications. Less than 1% of cases develop Guillain-Barré syndrome (Chapter 388) and typically 7 to 10 days after the onset of symptoms and after the resolution of fever. Children who were exposed to Zika virus in utero are at risk for a wide range of disabilities, including long-term learning disabilities, neurocognitive defects, and abnormal visual and auditory function resulting in long-term disability.

TOGAVIRIDAE

CHIKUNGUNYA VIRUS

DEFINITION AND EPIDEMIOLOGY

Chikungunya virus, which is in the *Alphavirus* genus, is an important cause of large epidemics of fever, arthralgia, and arthritis in tropical and subtropical regions throughout the world. Similar to other alphaviruses, Chikungunya virus is an enveloped, plus-strand RNA virus with icosahedral symmetry. The virions are 60 to 70 nm in diameter, and the lipid envelope is decorated with viral glycoproteins, which form heterodimers that are grouped into trimers that form 80 projections on the virion surface.

Chikungunya virus is a mosquito-borne virus that was first characterized in Tanzania but is now transmitted globally, especially where the primary vector, *A. aegypti*, is active. In addition to occasional outbreaks in Africa and Asia, a large outbreak on Reunion Island infected about 25% of the population in 2005. Since then, Chikungunya virus has produced epidemic fever, arthralgia, and arthritic disease in 114 countries and territories in India, Southeast Asia, Africa, Oceania/Pacific islands, South America, and Central America (E-Fig. 352-3).

PATHOBIOLOGY

Transmission of Chikungunya virus is maintained in a sylvatic cycle between nonhuman primates and *Aedes* species of mosquitoes. Chikungunya virus can also maintain large urban epidemics with transmission between primarily *A. aegypti* or *A. albopictus* mosquitoes and humans. Following a bite from an infected mosquito, Chikungunya virus replicates in the dermal tissue and spreads to draining lymph nodes and the spleen, thereby resulting in viremia that may precede the onset of symptoms by 2 to 3 days. During acute viremia, direct infection of joint tissue, muscles, skin, and the central nervous system occurs, typically after 6 to 8 days of infection. The duration and magnitude of viremia are sufficient to transmit Chikungunya virus from humans to uninfected *A. aegypti* mosquitoes, thereby resulting in large urban outbreaks in tropical and subtropical regions.

CLINICAL MANIFESTATIONS

Approximately 3 to 28% of infected individuals remain asymptomatic, but the remainder develop symptomatic illness characterized by fever (>102° F/39° C) and arthralgias. A maculopapular rash, which develops 4 to 8 days after the onset of fever, involves the trunk, extremities, palms, soles of feet, and face. Other symptoms may include headache, myalgias, arthritis, conjunctivitis, nausea, and vomiting. Joint symptoms, which can be debilitating, are typically manifested as a polyarthritis involving the hands, wrists, and ankles, although more proximal joints also can be involved. Patients may also develop myocarditis, hepatitis, retinitis, acute renal disease, and meningoencephalitis.[14]

DIAGNOSIS

The differential diagnosis for Chikungunya virus includes other circulating arboviruses, such as dengue virus or Zika virus, as well as other causes of fever and arthralgias, including malaria (Chapter 316), measles (Chapter 338), enteroviruses (Chapter 349), leptospirosis (Chapter 298), and other endemic infections. Preliminary diagnosis is based on a compatible syndrome associated with exposure to a geographic region with Chikungunya virus transmission. During acute infection, diagnosis can be made using Chikungunya virus nucleic acid amplification testing of the serum. Detection of CHIKV IgM early in the course of disease or a four-fold increase in CHIKV IgG would support a diagnosis of acute CHIKV infection.

TREATMENT, PREVENTION, AND PROGNOSIS

Similar to other arboviruses, treatment is supportive with oral or intravenous fluids and with acetaminophen to reduce fever and pain. NSAIDs (Table 26-4) can be used to treat symptoms once dengue is ruled out. A safe and immunogenic vaccine is undergoing clinical trials.[15] Acute symptoms resolve in 7 to 10 days, and fatalities are rare. Some patients (5 to 80%) have chronic rheumatologic symptoms (e.g., polyarthritis, tenosynovitis, chronic arthralgias, Raynaud syndrome) and persistent and prolonged fatigue for several months after the acute infection. In some cases, the arthritis, pain, and swelling become chronic.

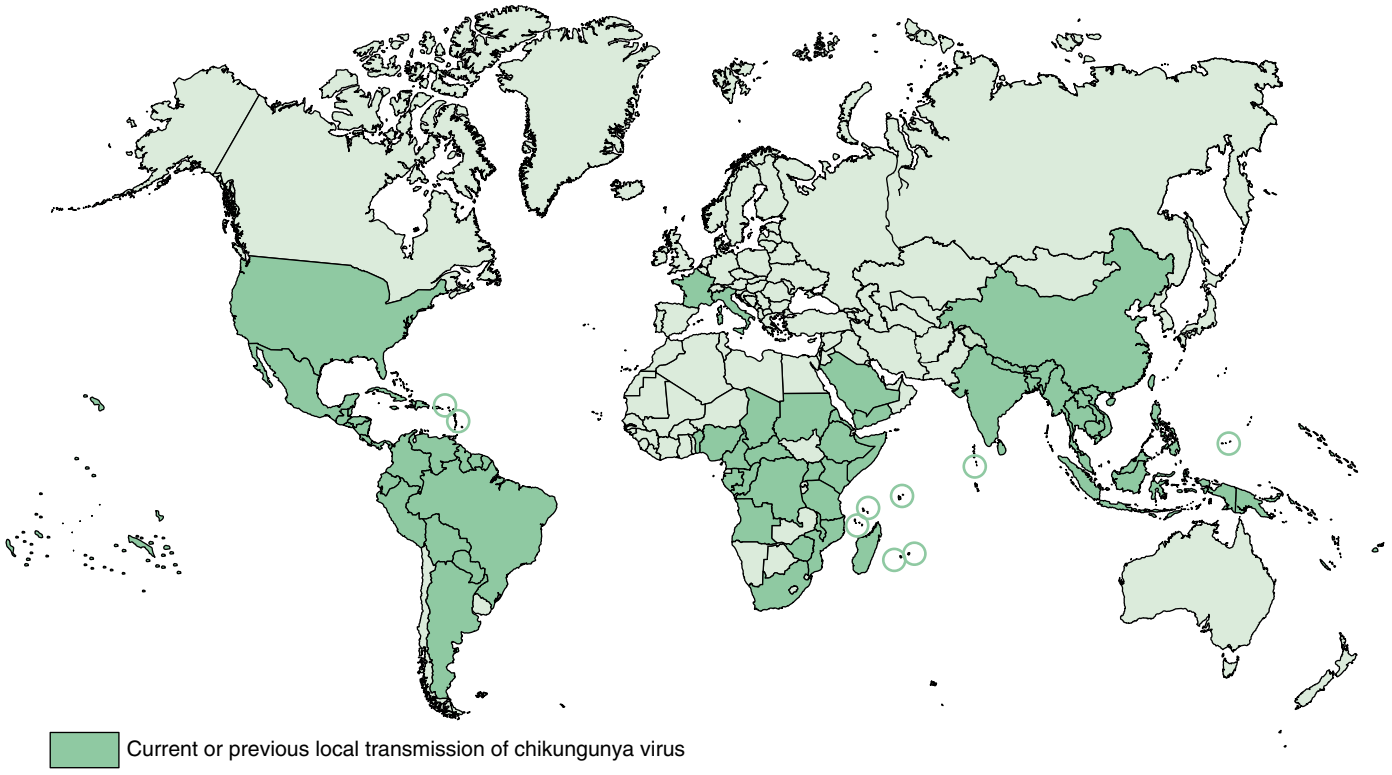
O'NYONG-NYONG

DEFINITION AND EPIDEMIOLOGY

O'nyong-nyong virus is an alphavirus that causes a fever-myalgia syndrome similar to Chikungunya virus, is endemic to sub-Saharan Africa, and was first identified following an outbreak of fever and arthralgia syndrome in Uganda in 1959. O'nyong-nyong virus quickly spread throughout eastern and western Africa causing outbreaks of disease with infection rates ranging from 3 to 45%. Current seroprevalence rates vary from 0.8% in inland Kenya to as high as 56% in a coastal community in Kenya.

PATHOBIOLOGY

O'nyong-nyong virus is unique among alphaviruses in that it is primarily spread by night-feeding *Anopheles* mosquitoes, including *A. funestus* and *A. gambiae*, which are also malaria vectors. O'nyong-nyong virus causes large outbreaks



E-FIGURE 352-3. Chikungunya distribution based on past and current epidemics. (Adapted from https://www.cdc.gov/chikungunya/geo/index.html.)

of febrile disease and then will retreat, likely circulating in an enzootic cycle between vectors and natural reservoir hosts that are not currently known.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The incubation period is approximately 8 days following initial infection, and about 25% of laboratory-confirmed cases develop symptoms. O'nyong-nyong virus shares many of the clinical features of Chikungunya virus, including sudden onset of high fever, joint pains primarily in large joints,[16] headache, diffuse maculopapular rash on the chest and limbs, and conjunctivitis.

Viremia may be detected in serum in the first 7 days of illness using RT-PCR. Detectable levels of IgM antibodies appear during the second week of illness and can persist for several months.

TREATMENT, PREVENTION, AND PROGNOSIS

There is no specific therapeutic for O'nyong-nyong virus disease or vaccine available to prevent infection. The acute illness is self-limited, but patients can have prolonged large-joint arthritis that results in significant morbidity.

ROSS RIVER FEVER VIRUS (EPIDEMIC FEBRILE POLYARTHRITIS)

DEFINITION AND EPIDEMIOLOGY

Ross River fever virus, which is a member of *Togaviridae* virus, causes an acute-onset, febrile illness characterized by rash and arthralgia. The virus is seen in tropical and temperate regions in Australia (especially Queensland and New South Wales), Papua New Guinea, western New Guinea, and Pacific islands in the Australian geographic zone.

Most cases occur in spring through autumn after heavy rainfall.[17] *Aedes* mosquitoes are the major vector near saltwater, whereas *Culex annulirostris* is a freshwater vector. Intermediate hosts include domestic animals, rodents, and marsupials. Barmah Forest virus, which also is associated with epidemic febrile polyarthritis in Australia, may present in a similar fashion.

PATHOBIOLOGY

Following a bite from an infected mosquito and replication in local tissue-resident macrophages and dendritic cells, viremia results with and distribution to other tissues, including the spleen, muscle tissue, and joint tissue. Viral antigen can be detected in monocytes and macrophages early in infection, but intact virus is not identifiable by electron microscopy or cell culture. Dermal vessels show mild perivascular mononuclear cell infiltrates, mostly T lymphocytic, in erythematous and purpuric areas. Vessels in purpuric areas also show erythrocyte extravasation. Antigen can be seen in involved skin, and viral RNA can be seen in joint fluid.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The abrupt onset of arthralgia can precede or follow a rash that is typically maculopapular, predominantly on the trunk and extremities, and sometimes pruritic. The arthralgia is usually asymmetrical, migratory, and severe, with a predilection for the hands.[18] Arthralgias tend to be worse in the morning, and about 30% of patients have synovitis. Classic carpal tunnel syndrome may occur. Fever, which is usually mild to moderate and persists for several days, may also be accompanied by headache, myalgia, nausea, respiratory symptoms, photophobia, and lymphadenopathy.

Since most patients are viremic for up to 7 days after the onset of symptoms, RT-PCR can detect viral RNA in most patients. Synovial fluid shows a monocytic cell predominance.

TREATMENT AND PROGNOSIS

NSAIDs are recommended for symptomatic relief. Symptoms generally resolve over weeks to months but may persist for up to 3 years.

SINDBIS

Sindbis virus, which is a febrile illness with arthralgia and rash, has been reported primarily in Scandinavia and nearby Russia but also in southern and central Africa as well as Australia. About 3% of the population of northern Sweden is seropositive. Mosquito vectors are *Aedes, Culex*, and *Culiseta* species, and the intermediate hosts are birds.

The virus can be isolated from skin lesions. Antiviral IgM is long-lasting, thereby suggesting persistent infection or an autoimmune process.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients present with a macular rash and arthralgia of the hands, feet, wrists, elbows, ankles, and knees. Tendinitis can involve hand extensor and foot plantar tendons. Fever and constitutional symptoms, if present, are rarely severe. Macules on the torso, extremities, and even the palms can become papular and vesiculate.

Positive IgM titers support the diagnosis, although they can remain elevated for 3 to 4 years after infection. Molecular diagnostic techniques (RT-PCR) are not presently available for routine diagnosis.

TREATMENT AND PROGNOSIS

NSAIDs can help with symptoms. Nonerosive chronic arthropathy persists in about 50% of patients for 2.5 years after infection and may persist for up to 6 years.[19]

MAYARO FEVER

DEFINITION AND EPIDEMIOLOGY

Mayaro virus is a positive-sense, enveloped, single-stranded RNA alphavirus. It is the etiologic agent of Mayaro fever, which is an emerging virus in Central and South America. Mayaro fever is an acute febrile illness that has been seen in Trinidad, Bolivia, Brazil, and Peru. *Haemagogus* mosquitoes in tropical rainforests are the vector, and monkeys serve as the reservoir. However, Mayaro virus has infected a wide range of *Aedes* and *Culex* mosquito species and a wide range of mammalian species, thereby increasing the likelihood of future geographic spread. Imported cases have been documented in the United States and in Europe after travel to the endemic regions, and it is expected to cause more travel-related illnesses in the United States and Europe with its increased spread in the Caribbean islands and Central America.

PATHOBIOLOGY

Most human cases occur in close association with tropical rainforests. The reservoir for Mayaro virus is not known, but high-grade viremia has been found in nonhuman primates. Following the bite of a mosquito, local replication of the Mayaro virus in skin tissue likely leads to viremia and seeding of distant sites. Following dissemination, virus can cause end-organ infection and injury to joint tissue, muscles, and the spleen.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

After an incubation period of 1 to 12 days, the clinical onset is sudden, with fever, chills, headache, arthralgias, and sometimes joint swelling of the hands and feet.[20] Neurologic manifestations and myocarditis have also been described. After the fever resolves in 3 to 7 days, about two-thirds of patients develop a maculopapular rash on their trunk and extremities. RT-PCR of blood has a high sensitivity and specificity for the diagnosis.

TREATMENT AND PROGNOSIS

Recovery is typically complete with supportive therapy, including NSAIDs, but arthralgias can persist for 6 months or more.

BUNYAVIRALES

RIFT VALLEY FEVER

DEFINITION AND EPIDEMIOLOGY

Rift Valley fever virus is a member of the Bunyavirales order and *Phlebovirus* family, with a virion characterized by a lipid envelope containing a tripartite, single-stranded, negative- or ambisense RNA genome. The lipid envelope is decorated with viral glycoproteins, which function as viral attachment proteins.

Rift Valley fever virus, which was first identified in sheep in the Rift Valley province of Kenya in 1931, is endemic throughout sub-Saharan Africa, where it causes epizootic animal outbreaks that result in large numbers of abortions in cattle, sheep, and other livestock, especially during periods of heavy rain, when several species of mosquitoes can spread the infection to humans. During one outbreak in Egypt, over 200,000 people were infected and over 600 died. The seroprevalence in livestock in endemic regions varies from 0.5 to 93% depending on recent epidemics, animal species, and vaccination approaches. During interepidemic periods, the seroprevalence in animals drops to about 2 to 3%.

PATHOBIOLOGY

Rift Valley fever virus is transmitted to humans by the bite of infected *Aedes* species and *Culex* species mosquitoes, but infection can also result from the ingestion of unpasteurized milk, exposure to the blood of an infected animal, or even from the aerosol from aborted material from infected livestock.[21] Following exposure to Rift Valley fever virus, the virus infects antigen-presenting cells, thereby resulting in suppression of the type 1 interferon response, death of infected macrophages and dendritic cells, and wide dissemination of the virus to kidney, liver, adrenal gland, and endothelial cells. The result is an excessive pro-inflammatory cytokine and chemokine response, microcirculatory dysfunction, and impairment of the coagulation system, sometimes resulting in edema, hemorrhage, and disseminated intravascular coagulation.

CLINICAL MANIFESTATIONS

Rift Valley fever virus can cause asymptomatic infection or a self-limited febrile illness, but severe disease occurs in approximately 1 to 2% of infections. Following an incubation period of 2 to 6 days, clinical symptoms include fever, headache, myalgias, back pain, vertigo, anorexia, and photophobia. The fever persists for 5 to 7 days, with a convalescent period that can persist for several days to a month. About 1 to 3 days after the primary symptoms resolve, some patients develop severe illness characterized by lymphopenia, hepatitis with elevated aminotransferase levels, jaundice, severe thrombocytopenia, and hemorrhage (see Chapter 351). Other manifestations of severe disease can include macular edema, miscarriage, and encephalitis.

DIAGNOSIS

Definitive diagnosis requires detection of virus RNA by RT-PCR in serum or plasma, detection of IgM and IgG antibodies, or detection of Rift Valley fever virus antigen in infected tissue. Because the periods of viremia and antigenemia are short, testing of acute and convalescent sera for IgM and IgG is often helpful. Since most human infections are asymptomatic or flulike in nature, the index of suspicion should remain high in endemic regions with increased rates of spontaneous abortions in sheep or cattle.

TREATMENT, PREVENTION, AND PROGNOSIS

No specific treatment other than general supportive care is available. Vaccines for livestock can produce long-lasting protection after a single dose and limit epizootic spread to humans, but there is no currently licensed human vaccine. Severe disease can carry a mortality rate of 5 to 70%.

PHLEBOTOMUS FEVER

DEFINITION AND EPIDEMIOLOGY

Phlebotomus fever or sandfly fever, which is an acute and self-limited febrile illness, is caused by single-stranded RNA viruses in the *Bunyaviridae* family. The virus is 80 to 120 nm in diameter with a lipid envelope and three genomic segments. The virus is transmitted by bites of *Phlebotomus* sandflies in the northern Mediterranean, western Europe, Turkey, the Middle East, western India, and Pakistan. The *Lutzomyia* fly species can transmit the virus in Central America. Sandflies exhibit hopping behavior during feeding but can still disperse widely, with travel distances up to 1 to 2 kilometers.

PATHOBIOLOGY

The pathogenesis of phlebotomus fever is not well defined. Following the bite of an infected sandfly, the virus likely replicates in tissue-resident monocyte-derived dendritic cells, thereby resulting in a viremia that seeds hepatocytes, adrenocortical cells, and renal tubular epithelial cells.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

After an incubation period of 2 to 6 days, an acute febrile illness is associated with constitutional symptoms, a macular or urticarial rash, headache, altered taste, photophobia, myalgia, arthralgia, and even pleurodynia. Fever typically persists for 2 to 4 days, but about 15% of patients have recrudescence 2 to 12 weeks later. Laboratory testing is often notable for thrombocytopenia, leukopenia, and increased levels of creatinine kinase, aspartate aminotransferase, and alanine aminotransferase. Some patients develop aseptic meningitis with a mild CSF pleocytosis. The diagnosis can be made by serology for virus-specific IgG and IgM antibodies in serum. RT-PCR can detect the viral genome but is less sensitive owing to the short duration of viremia.

TREATMENT, PREVENTION, AND PROGNOSIS

Complete recovery follows supportive treatment. Sandflies, which feed in the early evening, are small enough to pass through mosquito netting. Use of insect sprays locally is effective in decreasing risk.

MENINGITIS AND ENCEPHALITIS SYNDROME

FLAVIVIRIDAE

JAPANESE ENCEPHALITIS

DEFINITION AND EPIDEMIOLOGY

Japanese encephalitis virus, which is a member of the family *Flaviviridae* and *Flavivirus* genus, is a mosquito-borne virus that causes large outbreaks of viral encephalitis, predominantly in children and young adults.[22] An estimated 60,000 annual cases occur throughout Southeast Asia, India, the western Pacific islands, and northern Australia. In endemic regions, the majority of cases occur in children, and the risk of severe disease decreases with increasing age.

PATHOBIOLOGY

Japanese encephalitis virus is transmitted by *Culex tritaeniorhychnus* and related ground-dwelling mosquitoes, principally in flooded rice fields, with pigs and aquatic birds acting as the amplifying hosts. After the bite of an infected mosquito, the virus replicates in the skin, with subsequent spread to the draining lymph nodes and spleen. Secondary viremia results in end-organ infection, including the spinal cord and brain tissue, where Japanese encephalitis virus infection causes apoptotic cell death accompanied by inflammatory immune responses.

CLINICAL MANIFESTATIONS

The majority of infected individuals are asymptomatic, but patients can develop fever, headache, nausea, vomiting, abdominal symptoms, aseptic meningitis, or encephalitis following an incubation period of 6 to 16 days. About 0.5% of infections progress to encephalitis or meningoencephalitis, which is characterized by excitability, delirium, seizures, limb tremors, and involuntary movements such as myoclonus. Cerebellar or spinal cord involvement can present with ataxia or limb paresis, including lower motor neuron–type weakness.

DIAGNOSIS

Viremia has typically resolved by the time that an immune-competent patient presents with disease, so the diagnosis is made by Japanese encephalitis virus–specific IgM antibody testing of the serum. Lumbar puncture is recommended and typically shows a CSF pleocytosis, with 10 to 500 white blood cells/μL (often with a polymorphonuclear cell predominance early in the course of disease but with a lymphocyte predominance later), an elevated protein level (50 to 100 mg/dL), and a normal glucose level. Japanese encephalitis virus–specific IgM antibodies in the CSF have a sensitivity of 65 to 70% and a specificity of 90 to 100%. An alternative is to find a four-fold increase in IgG antibody titers to Japanese encephalitis virus in convalescent as compared with acute serum samples. On MRI, Japanese encephalitis virus characteristically causes a subcortical encephalitis with a T2 hyperintense signal, most commonly in the thalamus and occasionally in the midbrain, basal ganglia, and cerebellum.

TREATMENT, PREVENTION, AND PROGNOSIS

No specific therapy is available for patients. In endemic regions, a live-attenuated vaccine is highly efficacious,[A7] even after the first dose of the two-dose regimen. Since the risk among travelers to endemic areas is approximately 1 in 5000 to 20,000 per week of travel, vaccination is recommended with two doses at 0 and 28 days. Japanese encephalitis virus has a 20% case-fatality rate and a 30 to 50% rate of long-term neurologic and neuropsychiatric complications, including parkinsonism, seizure disorders, paresis, cognitive impairment, and neuropsychiatric disorders.

WEST NILE VIRUS

DEFINITION AND EPIDEMIOLOGY

West Nile virus is a member of the *Flavivirus* genus and part of the Japanese encephalitis virus complex of viruses along with St. Louis encephalitis virus and Usutu virus. West Nile virus is widely distributed in many parts of Africa, West Asia, the Middle East, Eastern Europe, Australia, and the Americas. It is now endemic throughout the continental United States and Canada, where it is the leading cause of mosquito-borne viral encephalitis (Chapter 383), with annual outbreaks in the late summer and early fall.

West Nile virus is maintained in an enzootic transmission cycle between *Culex* spp of mosquitoes and perching birds, with resulting epizootic spillover into dead-end hosts, primarily humans and horses. Since 1999, over 50,000 reported cases of West Nile virus disease have resulted in 2390 deaths in the United States.[23] About 80% of infected individuals are asymptomatic, and the risk of developing symptoms and severe complications increases with age.

PATHOBIOLOGY

In the United States, the majority of infections follow the bite of a *Culex* mosquito, but transmission also can occur via blood transfusion or organ transplantation from viremic donors. Following infection from a mosquito bite, the virus replicates in local skin tissue and dendritic cells and then drains to regional lymph nodes, where West Nile virus infects additional macrophages and monocytes, thereby resulting in a primary viremia. Following the primary viremia, the spleen becomes infected and causes a secondary viremia, with fever and seeding of the brain, gastrointestinal neurons, and kidneys. Humans do not have a sufficient viremia to transmit West Nile virus to uninfected mosquitoes.

CLINICAL MANIFESTATIONS

Approximately 80% of infected individuals are asymptomatic. About 90% of symptomatic individuals develop only a self-limited, febrile illness termed West Nile virus fever and characterized by fever, myalgias, retrobulbar pain, headache, and a diffuse maculopapular rash on the chest and extremities.[24] Only 1 in 150 infected individuals develops meningitis or encephalitis. Meningitis is characterized by fever, photophobia, headache, and neck pain without focal neurologic abnormalities. Encephalitis is characterized by altered mental status, ataxia, tremor, myoclonus, parkinsonism, and/or varying degrees of flaccid paralysis.

DIAGNOSIS

Detection of West Nile virus RNA in the serum and CSF by RT-PCR assays is highly specific, but it is unusual to detect RNA except in immunocompromised patients (Fig. 352-1). West Nile virus–specific antibody testing detects anti–West Nile virus IgM and IgG in serum and CSF. IgG levels can be positive based on past exposure or cross-reactivity to other flaviviruses (e.g., St. Louis encephalitis virus), and West Nile virus–specific IgM sometimes can persist for up to 12 months. As a result, serum and CSF antibody testing must be interpreted with the appropriate clinical syndrome and context.

CSF exhibits a lymphocytic pleocytosis, although 30 to 45% of patients may present with a neutrophil-predominant CSF pleocytosis, particularly early in the disease. CSF protein is typically elevated, and the glucose level is normal. MRI imaging, which is positive in 40 to 50% of patients, most commonly exhibits increased T2 hyperintense signal in the thalamus, basal ganglia, midbrain, and occasionally the medial temporal lobes (see Fig. 352-1).

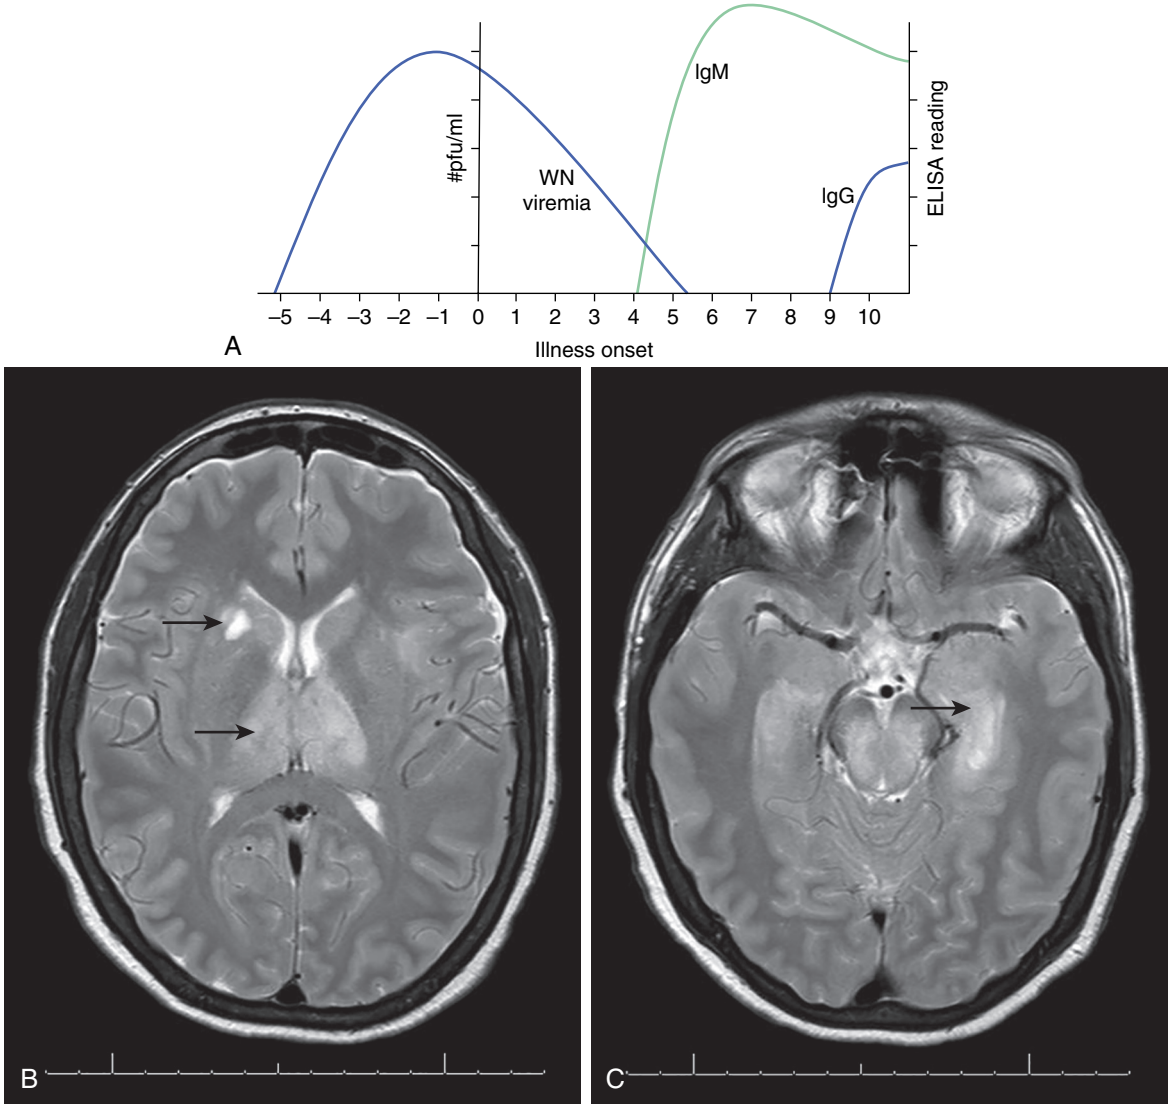


FIGURE 352-1. Diagnosis and imaging for West Nile (WN) virus disease. A, Graphic representation of timing for WNV RNA and serology detection over time. (A, Adapted from www.cdc.gov/westnile/healthcareproviders/healthCareProviders-TreatmentPrevention.html.) Magnetic resonance imaging (MRI) results from a patient with WNV encephalitis showing T2 hyperintense signal in the (B) thalamus and caudate nucleus and (C) medial temporal lobe and midbrain. *Arrows* indicate regions of increased signal. ELISA = enzyme-linked immunosorbent assay; Ig = immunoglobulin; pfu = plaque-forming unit.

TREATMENT, PREVENTION, AND PROGNOSIS

No therapy has proven efficacy. In the United States, screening of donor blood and organs using nucleic acid amplification testing has significantly decreased the risk of transmission. Following West Nile virus encephalitis or flaccid paralysis, recovery can be prolonged and associated with long-term neurologic deficits in 30 to 40% of survivors.[25] Common long-term symptoms and disabilities include fatigue, myalgias, paralysis, cognitive and memory deficiencies, and parkinsonism.

POWASSAN VIRUS

DEFINITION AND EPIDEMIOLOGY

Powassan virus is a member of the genus *Flavivirus* and an emerging cause of tick-borne viral encephalitis in the Mid-Atlantic, northeastern, and upper Midwestern regions of the United States,[26] as well as in Canada and far eastern Russia. Since 2010, the United States has reported over 180 cases of Powassan virus disease, but more than 20% were in the most recent years. Powassan virus is maintained in enzootic cycles between *Ixodes* species (*I. scapularis* and *I. cookie*) and small mammals and white-tailed deer. Two lineages, the Powassan virus and the deer-tick virus, have a 14% divergence in nucleotide sequence of their envelope glycoproteins. The apparent increase in case numbers is likely due to increased surveillance and detection, increased density and spread of tick populations, and increased human-tick contacts. Powassan virus also can be transmitted by blood transfusion and probably by organ transplantation from viremic donors.

PATHOBIOLOGY

Ixodes sp of ticks become infected by feeding on a viremic host or cofeeding with an infected tick. When infected ticks bite and secrete saliva into humans, who serve as dead-end hosts during summer months, the virus is inoculated into the skin and can replicate in the epidermis and dermal cells as well local and regional dendritic cells and macrophages. Following viral replication, the virus spreads to local lymph nodes and the spleen, before then spreading to end organs such as the CNS.

CLINICAL MANIFESTATIONS

Following infection from a Powassan virus–infected tick, the incubation period ranges from 8 to 34 days followed by a prodrome of 1 to 3 days characterized by fever (>40° C), generalized malaise, myalgia, nausea, and sometimes a maculopapular rash. The rates of asymptomatic or mild infection are unknown, but about 90% of reported cases have had neuroinvasive disease, with meningitic symptoms such as meningismus and photophobia, or with signs and symptoms of encephalitis, including altered mental status, respiratory distress, ataxia, tremor, and ocular involvement.

DIAGNOSIS

I. scapularis is able to transmit Powassan virus within 15 minutes of attachment, so a history of removal of a tick in an endemic region should indicate potential infection. Routine complete blood count may exhibit leukopenia (white blood cell count <4000/μL) and thrombocytopenia (<150,000/μL). If a patient presents early in the course of disease, PCR of blood and CSF may provide a diagnosis, particularly in immunocompromised patients. However, since the viremia has usually resolved by the time a patient presents with symptoms, serology (Powassan virus–specific IgM capture ELISA and indirect IgG ELISA) to detect antibody in the serum and IgM antibody in the CSF is the principal diagnostic approach. The CSF, as with other neuroinvasive arboviruses, typically exhibits a neutrophilic or lymphocytic pleocytosis, elevated protein level, and normal glucose level.

TREATMENT, PREVENTION, AND PROGNOSIS

There is no specific therapeutic option or vaccine for Powassan virus infection. Vaccines are available in eastern Europe and Russia for the closely related tick-borne encephalitis virus, but there is no evidence that these vaccines provide significant cross-protection against Powassan virus. An mRNA vaccine candidate for tick-borne flaviviruses exhibited protection in a murine model of Powassan virus. The reported case-fatality rate is about 10%, and about 50% of survivors have long-lasting neurologic deficits, including headaches, muscle weakness, focal paralysis, or neurocognitive deficiencies.

OTHER TICK-BORNE *FLAVIVIRIDAE*

DEFINITION AND EPIDEMIOLOGY

Louping ill, Alongshan virus, and tick-borne encephalitis are tick-borne viruses that can cause hemorrhagic fever (Chapter 351) but can also cause meningoencephalitis.[27] Louping ill virus is found in Britain and Alongshan virus in northeastern China.[28] Tick-borne encephalitis is seen in eastern Europe and far eastern Russia with more than 2000 cases reported each year. Louping ill causes sporadic cases of encephalitis in Scotland, northern England, and Ireland. Both louping ill and tick-borne encephalitis are similar to Powassan virus and other flaviviruses, with a single-stranded, positive-sense RNA genome contained in a virion that consists of a host-derived lipid envelope decorated with envelope and membrane proteins. Alongshan virus is derived from a novel emerging *Flaviviridae* group and is characterized by four positive-stranded RNA segments with poly-A tails enclosed in an enveloped virion decorated with the VP3 structural protein.

PATHOBIOLOGY

Tick-borne encephalitis virus and other tick-borne viruses are transmitted following a tick bite, most commonly of an infected *Ixodes* species tick. Ticks become infected after feeding on a vertebrate host, such as a small rodent, or can obtain the virus transtadially (transmission across tick development from larva to nymph to adult) or transovarially (from adult female to eggs). Infection may also follow consumption of unpasteurized milk or cheese from goats, sheep, or cows. During a blood meal, virus is excreted from the salivary glands of an infected tick, thereby resulting in localized infection of mononuclear cells and resident tissue macrophages in the skin. Virus replicates and spreads to regional lymph nodes and to the spleen.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Tick-borne encephalitis, which is by far the most common of these diseases, may be asymptomatic or begin with a flulike illness after a 1- to 2-week incubation period. The initial phase of the symptomatic illness is characterized by fever, myalgias, fatigue, and influenza-like symptoms during the first week. After about a week of usually mild symptoms, about 65 to 70% of patients clear the infection. However, the remaining 30% of patients develop a second phase of viremia associated with central nervous system infection that is characterized by meningitis or meningoencephalitis. The neurologic disease can be relatively mild but can also manifest as altered consciousness, bulbar paralysis, seizures, and paralysis. Louping ill and Alongshan viruses have a similar clinical course.

RT-PCR of blood can make the diagnosis in the first phase of the disease, but serologic diagnosis is required after neurologic symptoms develop.

TREATMENT, PREVENTION, AND PROGNOSIS

Treatment is supportive. A vaccine against tick-borne encephalitis is available and used in the general population in Austria and eastern Europe and in high-risk workers in Russia[29] with excellent results. Prognosis is generally benign with 1 to 2% mortality rate in Europe, but the mortality rate is 20% or so in far eastern Russia.

ST. LOUIS ENCEPHALITIS

DEFINITION AND EPIDEMIOLOGY

St. Louis encephalitis virus is closely related to Japanese encephalitis, Murray Valley encephalitis, and West Nile viruses. The virus has caused periodic epidemics of up to 2000 cases in North America (primarily in the Ohio-Mississippi River basin, eastern and central Texas and Florida, and western states, usually between July and September) as well as in the Caribbean and Argentina.[30]

PATHOBIOLOGY

The vectors are *Culex pipiens*, *Culex nigripalpus*, and *Culex tarsalis* mosquitoes that propagate in stagnant water, and the intermediate hosts are wild birds. Similar to other mosquito-borne flavivirus infections, St. Louis encephalitis virus is spread to humans as a dead-end host following a blood meal of an infected *Culex* sp mosquito. Virus replicates in tissue-resident dendritic cells and macrophages, followed by spread of virus to regional lymph nodes and the spleen. Secondary viremia following replication in splenic tissue results in infection of the central nervous system with predominant infection of neurons in basal ganglia, the thalamus, and other subcortical gray matter regions.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Over 99% of infections are asymptomatic. However, an incubation period of 4 to 21 days may precede nonspecific febrile symptoms followed by headache, drowsiness, altered consciousness, and meningeal or encephalitic signs. Seizures, which occur in 10% of patients, are a poor prognostic sign. A Guillain-Barré–like syndrome (Chapter 388) can occur acutely or during convalescence. Inappropriate antidiuretic hormone secretion

(Chapter 206) may occur. Virus in the genitourinary tract can cause incontinence, retention, microscopic hematuria, pyuria, proteinuria, and acute renal injury.

CSF shows a pleocytosis, initially neutrophilic and then lymphocytic, of up to 500 cells/μL, with an elevated protein level and normal glucose level. The electroencephalogram (EEG) typically shows frontal and temporal polymorphic delta activity, often with seizures.

Rapid diagnosis is by RT-PCR or by detecting IgM antibodies in serum and CSF. Later serologic diagnosis is made with acute and convalescent antibody titers.

TREATMENT, PREVENTION, AND PROGNOSIS

Treatment is supportive, and no vaccine is available. The case-fatality rate is negligible in persons younger than age 20 years but rises to 30% in patients over age 65 years. About 30 to 50% of adult survivors have persistent neuropsychiatric symptoms for 3 years or more.

MURRAY VALLEY AND ROCIO ENCEPHALITIS

Murray Valley encephalitis and Rocio encephalitis are caused by flaviviruses and cause clinical syndromes that are very similar to each other and to Japanese encephalitis. Murray Valley encephalitis, which is endemic in northern Australia and New Guinea, has caused limited epidemics in the Murray and Darling River valleys of Victoria and New South Wales, Australia. Rocio encephalitis in São Paulo State, Brazil, has caused epidemics of 1000 or more cases.

TOGAVIRIDAE

EASTERN EQUINE ENCEPHALITIS VIRUS

DEFINITION AND EPIDEMIOLOGY

Eastern equine encephalitis virus is a mosquito-borne virus, which is in the genus *Alphavirus* and is closely related to Western equine encephalitis virus and Venezuelan equine encephalitis virus. It has caused small, limited outbreaks (5 to 10 cases) annually in the eastern United States, but its incidence may be rising to about 40 cases per year as it spreads from its endemic areas along the Atlantic coast, Gulf Coast, and Great Lakes regions to other regions. Of its four lineages, group I causes the majority of disease in the United States, whereas groups II to IV primarily cause disease in horses in Central and South America. The virus exists in an enzootic cycle between the primary vector, *Culiseta melanura*, and birds. Multiple bridging mosquito vectors that feed on infected birds can spread the virus to a large variety of dead-end hosts, including equine species, humans, other birds, and livestock.[31]

PATHOBIOLOGY

Similar to other arboviruses, Eastern equine encephalitis virus is introduced by mosquito bite in the subcutaneous tissue with subsequent infection of epithelial cells and local dendritic cells and macrophages. The virus then drains to local lymph nodes, thereby resulting in viremia and spread to target organs like the CNS. After viremia peaks at days 2 to 4 postinfection, IgM and then IgG antibodies can be detected in the serum.

CLINICAL MANIFESTATIONS

The incubation period is 4 to 10 days, and initial symptoms include fever, chills, malaise, myalgias, and arthralgias. The initial systemic illness persists for approximately 1 to 2 weeks, followed by recovery for most patients. Clinical evidence of neuroinvasive disease, which typically develops within the first 3 to 5 days, includes headache, nausea, vomiting, weakness, and meningismus. The neuroinvasive disease is typically severe, with 25% of patients developing seizures, and 90% have a significantly altered mental status.

DIAGNOSIS

Similar to other neuroinvasive arboviruses, the CSF exhibits a lymphocytic pleocytosis, elevated protein level, and normal glucose level. However, encephalitis can cause a neutrophilic pleocytosis in the CSF, and about 75% of patients also have red blood cells in their CSF. RT-PCR testing of serum and CSF has a low sensitivity but a high specificity. The diagnosis is usually confirmed by IgG and IgM testing of the serum and CSF in specialized laboratories.

TREATMENT, PREVENTION, AND PROGNOSIS

Treatment is supportive. There are no approved therapies or vaccines. The overall mortality rate is 30 to 40%, and the majority of survivors have long-term neurologic sequelae[32] that require prolonged rehabilitation and care following infection. A new trivalent virus-like particle vaccine recently completed phase 1 trials[33] and may prove useful in the future.

WESTERN EQUINE ENCEPHALITIS

DEFINITION, EPIDEMIOLOGY, AND PATHOBIOLOGY

Western equine encephalitis is an uncommon disease with about 40 cases per year in the rural plains and Rocky Mountain areas of the United States. Cases are most frequent after snow melt or flooding, and diagnosed equine disease commonly precedes human cases. The disease has also been reported in Argentina. *Culex tarsalis* mosquitoes are the vector, and wild birds serve as the reservoir. The disease mostly affects the basal ganglia and thalami, where it causes focal necrosis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

After an influenza-like syndrome with fever, headache, and myalgia for 1 to 4 days, patients develop somnolence and lethargy that can progress to stupor, seizures, and coma, with death soon after coma develops. CSF typically shows less than 500 polymorphonuclear and then mononuclear white blood cells/μL and an elevated protein level. Diagnosis usually is achieved by IgM antibodies in serum or CSF, but RT-PCR testing of the serum and CSF is available at specialized reference laboratories.

TREATMENT, PREVENTION, AND PROGNOSIS

There is no specific therapy for Western equine encephalitis, so therapy is supportive. The case-fatality rate is 3 to 5%. Adults usually recover slowly but completely, but children are more likely to have chronic neurologic impairment.

VENEZUELAN EQUINE ENCEPHALITIS

DEFINITION, EPIDEMIOLOGY, AND PATHOBIOLOGY

Venezuelan equine encephalitis occurs in periodic outbreaks, which have been as large as 85,000 human cases in Venezuela, Colombia, Ecuador, Peru, and the Gulf Coast region of Mexico. *Aedes, Psorophora*, and *Mansonia* mosquitoes can serve as vectors, whereas equines are the principal hosts. Laboratory infections commonly occur in unvaccinated persons who work with infected animals or the virus, and the virus is a potential agent for biological warfare. Person-to-person spread can theoretically occur but seems very rare. Sporadic human disease has also been reported in Florida, where *Culex* mosquitoes are the vector and the hosts are small rodents. CNS changes include meningeal and perivascular inflammation, vasculitis, neuronal degeneration, and intracerebral hemorrhage. Hepatitis and interstitial pneumonitis also occur.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

After an incubation period of 2 to 5 days, patients have a self-limited, flulike illness that subsides in 4 to 6 days. However, encephalitis develops in about 4% of infected persons, especially children, and is characterized by seizures, stupor, spastic paralysis, coma, and respiratory failure. Residual neurologic damage occurs in severe cases. The CSF has up to 500 cells/μL, predominantly lymphocytes. Virus can be detected by RT-PCR from blood or from throat swabs. The diagnosis also can be confirmed by IgM immunoassay.

TREATMENT, PREVENTION, AND PROGNOSIS

Treatment is supportive. An experimental live-attenuated vaccine provides partial immunity for adult laboratory personnel. A DNA vaccine for Venezuelan equine encephalitis is under investigation. Epidemics and epizootics can be prevented by vaccinating equines. The case-fatality rate is less than 10% in adults, but patients with severe encephalitis may have persistent neurologic deficits.

BUNYAVIRALES

CALIFORNIA ENCEPHALITIS VIRUS/LA CROSSE VIRUS/JAMESTOWN CANYON VIRUS

DEFINITION AND EPIDEMIOLOGY

California encephalitis virus, La Crosse virus, and Jamestown Canyon virus are mosquito-borne RNA viruses that are members of the California encephalitis group of viruses. These viruses exhibit shared characteristics with other

Bunyavirales members, including a lipid-enveloped virion containing a tripartite, negative- or ambisense, single-stranded RNA genome.

La Crosse virus primarily causes neuroinvasive disease in children and is the leading cause of pediatric viral encephalitis in the United States, where it results in 50 to 100 cases per year.[34] In contrast, Jamestown Canyon virus preferentially causes neuroinvasive disease in adults, with several cases every year in the United States and Canada. Jamestown Canyon virus is widely distributed throughout the United States, whereas La Crosse virus cases are most common in the Gulf Coast and Midwest regions of the United States. California encephalitis virus, which is found in the western United States, is a rare human infection. All three viruses are maintained in enzootic cycles primarily between *Aedes* or *Ochlerotatus* spp of mosquitoes and multiple mammals, including ground squirrels, chipmunks, and white-tailed deer.

PATHOBIOLOGY

La Crosse virus, Jamestown Canyon virus, and California encephalitis virus are transmitted during summer months to humans, who serve as dead-end hosts following the bite of an infected female mosquito with virus in her salivary glands. Following a mosquito bite, these viruses replicate in local cutaneous tissue and distribute via viremia to end-organ tissues such as the CNS.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most infections are asymptomatic, but some patients can develop fever, chills, myalgias, nausea, and vomiting after a 3- to 7-day incubation period. In some patients, symptoms can progress to lethargy, aphasia, ataxia, focal weakness, and seizures. Neuroimaging is often negative, and CSF is characterized by lymphocytic pleocytosis, a high-to-normal protein level, and a normal glucose level. The EEG is abnormal in two thirds of patients with focal findings.

Detection of virus using RT-PCR assays may be helpful, especially in immunocompromised patients, but diagnosis usually relies on acute serology for virus-specific IgM in the serum and CSF. Neuroimaging is often negative, but an EEG is important to evaluate for underlying seizure activity.

TREATMENT, PREVENTION, AND PROGNOSIS

No antiviral therapy or vaccine is available for California encephalitis viruses. The mortality rate is less than 1%. Most patients recover without long-term sequelae, but some patients may have long-term complications such as seizures.[35]

REOVIRIDAE

COLORADO TICK FEVER VIRUS

DEFINITION AND EPIDEMIOLOGY

Colorado tick fever is a member of the family *Reoviridae*, a group of nonenveloped, double-stranded RNA viruses. The virions are relatively stable because of an inner icosahedral core that is surrounded by an outer capsid layer, which consists of four viral proteins.

Colorado tick fever is transmitted by the *Dermacentor andersoni* tick to humans in the western United States and western Canada at elevations of 4000 feet above sea level or higher.[36] About five cases are reported annually, predominantly from Colorado, Utah, Wyoming, Montana, Idaho, Oregon, Arizona, and California. The virus is maintained in an enzootic cycle between *D. andersoni* and small rodents and mammals. Humans come in contact with the enzootic cycle during recreational or other activities in forested regions where the virus circulates.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Following an incubation period of 1 to 14 days, symptoms include fever, chills, headache, myalgias, nausea, vomiting, abdominal pain, and a maculopapular rash on the trunk and arms. About 50% of patients develop a biphasic fever after initial improvement. About 1% of patients progress to neuroinvasive infection, most commonly characterized by meningeal symptoms, including photophobia and meningismus.

Recent outdoor exposure and tick bites in an endemic region are suggestive of infection. Most patients with biphasic illness present with leukopenia (white blood cell count <4000/μL) and thrombocytopenia (<150,000/μL). RT-PCR of blood is sensitive during the acute phase of infection.

TREATMENT, PREVENTION, AND PROGNOSIS

There is no specific therapeutic option or vaccine. Most patients recover completely, but many patients report prolonged fatigue and myalgias that may persist for several weeks. Even with neuroinvasive disease, mortality is less than 1%, and the majority of patients fully recover with no neurologic sequelae.

EPIDEMIOLOGY AND DIAGNOSIS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACQUIRED IMMUNODEFICIENCY SYNDROME

LARRY W. CHANG AND THOMAS C. QUINN

Four decades after the initial recognition of acquired immunodeficiency syndrome (AIDS) in 1980 and the subsequent identification of the human immunodeficiency virus (HIV; which exists in two types: HIV-1, which is the predominant circulating type, and HIV-2), the HIV pandemic remains one of the leading causes of death worldwide. Early efforts at prevention and treatment with antiretroviral drugs tempered the spread and decreased the fatality rate in some countries. In low-income countries, however, where the social, demographic, cultural, and economic impact of the AIDS epidemic had been the greatest, these gains were initially too limited and too slow to reverse the escalating trend of the epidemic. Over the past two decades, with the increased availability of antiretroviral drugs and other prevention interventions, including voluntary medical male circumcision, the rate of new HIV infections has decreased and mortality has declined in most settings.

GLOBAL STATISTICS

Since the HIV epidemic began in the first half of the 20th century, more than 79 million people have been infected with HIV and 36 million people have died of HIV.[1] At the end of 2020, according to estimates by the Joint United Nations Program on HIV/AIDS (UNAIDS), 37.7 million people were living with HIV (Table 353-1 and E-Fig. 353-1A). Adults constituted the majority of those infected; children (persons less than 15 years of age) accounted for 1.7 million of the infected. Globally, people living with HIV were evenly divided by gender, although there was substantial regional variation. Sub-Saharan Africa continued to have the majority of persons living with HIV and the highest HIV prevalence rates, but large epidemics are present worldwide (Fig. 353-1 and see Table 353-1). The continuing rise in the population of people living with HIV infection reflects the combined effects of continued HIV transmission and the beneficial impact of antiretroviral therapy, resulting in fewer deaths.[2]

In 2020, the 1.5 million people who became newly infected with HIV globally represented a decline of 31% since 2010 and a marked decline from the more than 3 million infections per year experienced during the peak of the epidemic in the 1990s (see E-Fig. 353-1B and Table 353-1). These declines have been most prominent among children, in whom new infections have decreased by 53% since 2010; decreases in adults have occurred more slowly. Despite this progress, declines remained well short of United Nation's 2020 targets of 500,000 infections per year. Progress has also been uneven across regions, with the steepest declines in new HIV infections in eastern and southern Africa (43%) compared with a troubling 43% rise in new infections in eastern Europe and central Asia. Low- and middle-income countries constitute more than 90% of new infections, and sub-Saharan Africa alone accounts for 58% of all new HIV infections globally.

The major mode of HIV transmission globally in 2020 was heterosexual transmission, although infections continue to spread at high rates among key populations such as men who have sex with men and people who inject drugs. These and other key populations continue to play important roles in all major regional epidemics (E-Fig. 353-2). Outside of sub-Saharan Africa, key populations and their partners accounted for 93% of new HIV infections in 2020. In sub-Saharan Africa, they accounted for 39% of new HIV infections. Globally, women acquire new HIV infections at roughly the same rate as men. However, new infections in young women aged 15 to 24 years were 80% higher than in men, a figure that is a particular concern because this age group accounted for 28% of all new HIV infections in 2020 and is part of an ongoing demographic youth bulge.

HIV continues to be a major source of global morbidity and mortality, although significant progress has been made in scaling up life-saving treatment. Deaths from HIV have declined from a peak of 1.9 million deaths in 2005 to 680,000 deaths in 2020 (Fig. 353-1C), likely owing to increased HIV treatment access and fewer new HIV infections. Gender disparities in mortality are substantial, with declines in deaths about 25% lower among men compared with women, likely because of higher HIV treatment uptake among women. There have been even sharper declines in child mortality due to HIV, with less than 90,000 deaths in 2020 compared with 210,000 in 2010, a 60% decline. Similar to reductions in new HIV infections, declines in deaths due to AIDS-related illnesses have been most pronounced in eastern and southern Africa. In contrast, there have been concerning increases in AIDS-related mortality in some countries in the Middle East and North Africa and eastern Europe and central Asia.

GLOBAL IMPACT AND RESPONSE

For the first two decades of the epidemic, fatality rates from AIDS steadily increased, and the average life expectancy in some countries in sub-Saharan Africa declined from 62 to 47 years of age. For example, in Haiti, life expectancy was nearly 6 years less than it would have been in the absence of AIDS. Cambodia experienced a reduction in life expectancy of more than 4 years. In 1995 in the United States, AIDS was the leading killer of Americans aged 25 to 44 years. Globally, HIV has now claimed an estimated 36 million lives.

Beginning in 1996 in high-income countries, the advent of combination antiretroviral therapy for HIV infection led to dramatic declines in HIV-associated mortality. In low-income and most middle-income countries, the Global Fund for AIDS, Tuberculosis, and Malaria as well as the United States President's Emergency Plan for AIDS Relief (PEPFAR) continue to provide treatment and care for people living with HIV globally, as well as resources for enhancing prevention efforts to stop further transmission. WHO treatment guidelines recommend antiretroviral therapy to all people living with HIV regardless of CD4 count and encourage universal access to HIV testing and care as part of a cascade framework of prevention and care (E-Fig. 353-3).

As of 2020, an estimated 84% of people living with HIV globally were aware of their HIV status. Among those who know their status, an estimated 87%

TABLE 353-1 REGIONAL HUMAN IMMUNODEFICIENCY VIRUS AND ACQUIRED IMMUNODEFICIENCY SYNDROME STATISTICS AND FEATURES AT THE END OF 2020*

REGION	ADULTS AND CHILDREN LIVING WITH HIV/AIDS	ADULTS AND CHILDREN NEWLY INFECTED WITH HIV	ADULT AND CHILD DEATHS DUE TO AIDS	PEOPLE ACCESSING TREATMENT
Eastern and southern Africa	20,600,000	670,000	310,000	16,000,000
Western and central Africa	4,700,000	200,000	150,000	3,500,000
North Africa and Middle East	230,000	16,000	7900	96,000

Latin America	2,100,000	100,000	31,000	1,400,000
Caribbean	330,000	13,000	6000	220,000
Eastern Europe and central Asia	1,600,000	140,000	35,000	870,000
Western and central Europe and North America	2,200,000	67,000	13,000	1,900,000
GLOBAL	37,700,000	1,500,000	680,000	27,500,000

*Numbers are rounded estimates from the Joint United Nations Programme on HIV/AIDS.
AIDS = acquired immunodeficiency syndrome; HIV = human immunodeficiency virus.

ABSTRACT

Within years of its recognition in the 1980s, HIV disseminated rapidly throughout the world, caused a massive global pandemic, and became one of the leading causes of death worldwide. Early efforts at prevention and treatment with antiretroviral drugs tempered the spread and decreased the fatality rate in some countries. In low income countries, however, where the social, demographic, cultural, and economic impact of the AIDS epidemic had been the greatest, these gains were initially too limited to reverse the escalating trend of the epidemic. Over the past two decades, with the increased availability of antiretroviral drugs and other prevention interventions, including voluntary medical male circumcision, the rate of new HIV infections has decreased and mortality has declined in most settings.

were on treatment, meaning that among all people living with HIV, about 73% were on treatment (Fig. 353-2). Of people on treatment, an estimated 90% were virally suppressed. Thus, in 2020, about 66% of all people living with HIV were virally suppressed. Although these figures represent remarkable progress from the early 2000s, significant gaps in testing and care remain. There is also considerable regional variation, with targets being met in some countries in western and central Europe and sub-Saharan Africa, but less so in eastern Europe and central Asia, the Middle East, and North Africa. Key success stories include Botswana, the first country in Africa to have reached UNAIDS 90-90-90 targets (90% of all people living with HIV will know their HIV status, 90% of those diagnosed are on antiretroviral therapy, and 90% of those on treatment are virally suppressed), and Eswatini, which has achieved a remarkable 97% reported viral suppression among all people living with HIV.

Regarding HIV treatment access, in 2020, an estimated 27.4 million people were on treatment, a dramatic increase from 2010 when only 7.8 million people had access to treatment (see Fig. 353-3). The trajectory of treatment access has been consistently upward for the past two decades, making the 2025 UNAIDS goals of 95% of people living with HIV on antiretroviral therapy a real possibility. People living with HIV also appear to be accessing antiretroviral therapy earlier after initial HIV infection. As a result of the rapid increases in treatment, life expectancy losses have been largely reversed in many countries (see E-Fig. 353-5). Among insured adults in the United States, life-expectancy at age 21 years is estimated to be another 57 years among HIV-treated patients compared with 64 years in uninfected people.[3] Globally, an estimated 16.6 million AIDS-related deaths have been saved due to antiretroviral therapy. Expanded treatment access to pregnant women living with HIV has already resulted in large declines in mother-to-child transmission of HIV.

Although progress in HIV prevention and treatment service access has been impressive, remaining challenges include a significant gender disparity, with men globally having lower knowledge of HIV status (82%) compared to women (88%), lower coverage of antiretroviral therapy (68%) compared with women (79%), and lower HIV viral suppression (62%) compared with women (72%). Young people living with HIV are less likely to know their HIV status, be on treatment, and have suppressed viral loads compared with older age

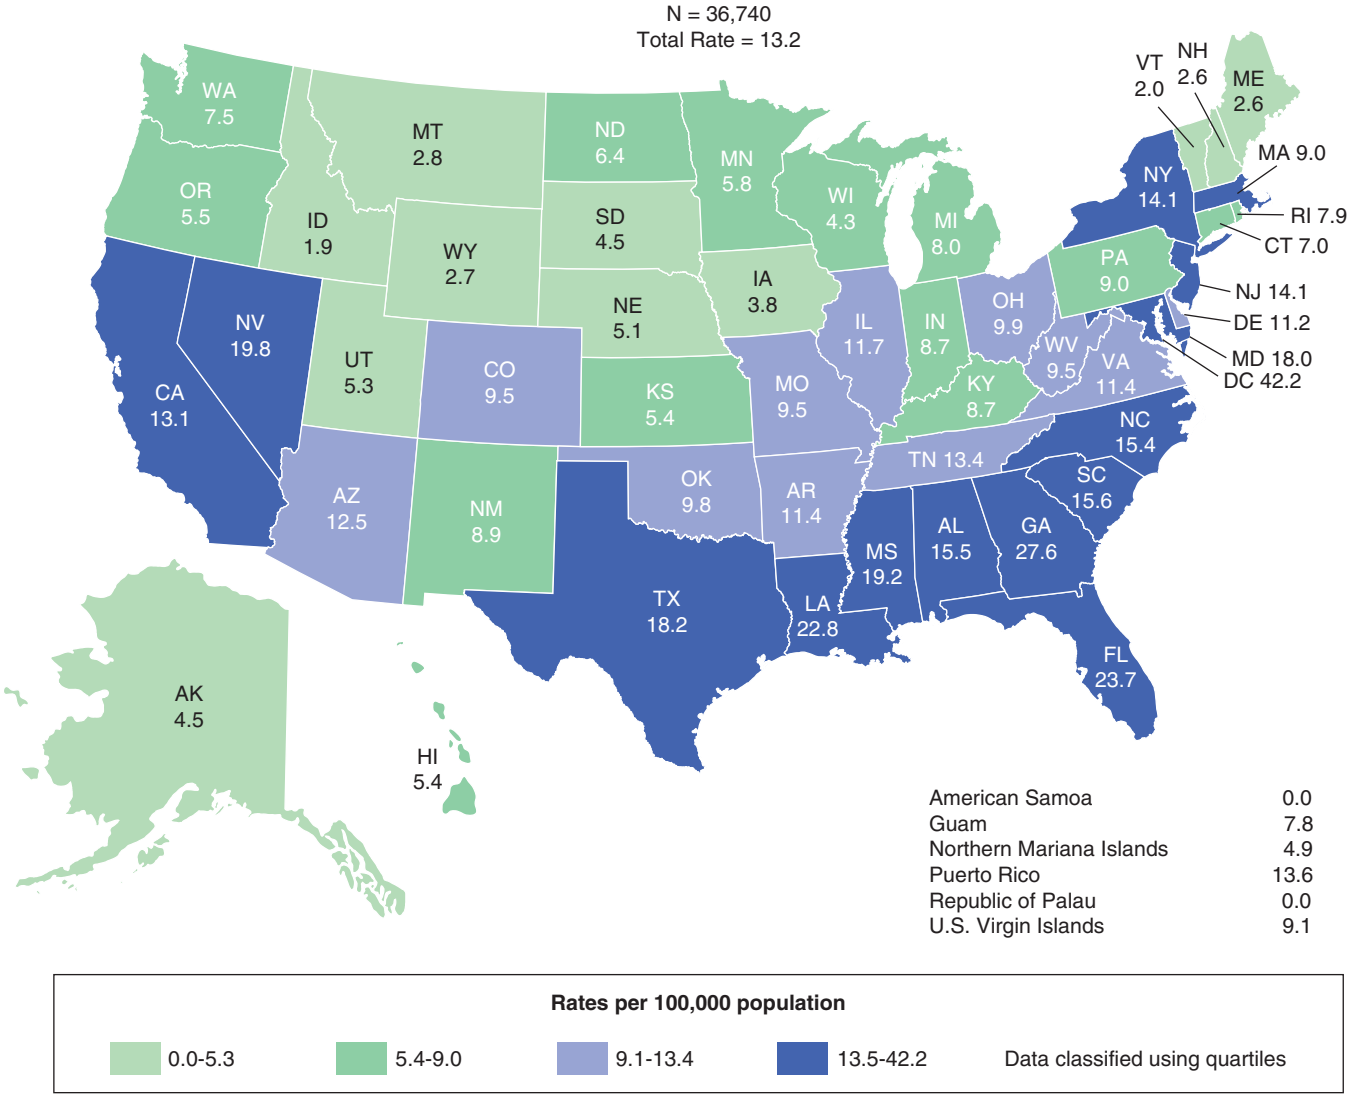

FIGURE 353-3. Rates of new diagnoses of human immunodeficiency virus infection among adults and adolescents, United States and 6 dependent areas, 2019. (Data from Centers for Disease Control and Prevention. HIV Surveillance Report, 2019.)

groups. Key populations, including sex workers, men who have sex with men, people who inject drugs, transgender people, and prisoners have additional barriers to testing and care, and resulting gaps in the HIV prevention and care cascade. HIV viral load testing access has increased rapidly, but more than half of persons on treatment remain without periodic viral load testing. In almost all target countries, global uptake of voluntary medical male circumcision, which reduces the risk for HIV acquisition among heterosexual men by about 55% and among men who have sex with men by about 20%,[A1] remains well below World Health Organization targets of 90%. Condoms, an effective HIV prevention tool, remain underused. Globally, comprehensive harm reduction programs for people who inject drugs, including needle-syringe programs and opioid substitution therapy, are also infrequently implemented. Finally, stigma, discrimination, gender-based violence, and HIV criminalization laws hinder HIV service uptake and retention, particularly among key populations.[4]

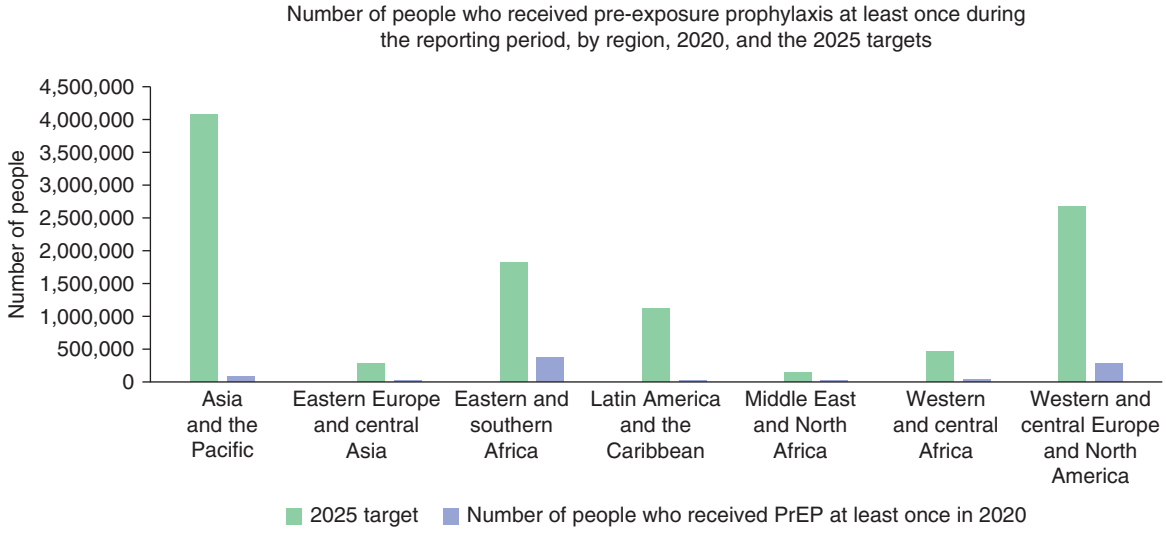
Numerous strategies can help the continuing global response to overcome existing challenges across the continuum of prevention and care. These strategies include the gradual expansion of preexposure prophylaxis (PrEP; Chapter 356),[5] either on-demand[A2] or daily[A3] among high-risk HIV-negative persons (E-Fig. 353-4),[6] as well as HIV self-testing and community-based testing to increase awareness of HIV serostatus. Differentiated care, a client-centered approach to HIV service delivery, is another approach being implemented that attempts to simplify and adapt HIV services to individual patient circumstances (e.g., stable people living with HIV on antiretroviral therapy with undetectable viral loads may need fewer provider visits, or a group of people living with HIV may form community-based treatment and support groups). In many global settings, new, less expensive, and improved antiretroviral therapy, such as integrase-based regimens, has improved access and outcomes. In the years to come, additional resources will be required to reach the additional millions of HIV-infected people who require treatment, retain those on treatment, and reach the millions of HIV-negative persons who would benefit from HIV prevention services.

REGIONAL EPIDEMICS AND RESPONSES

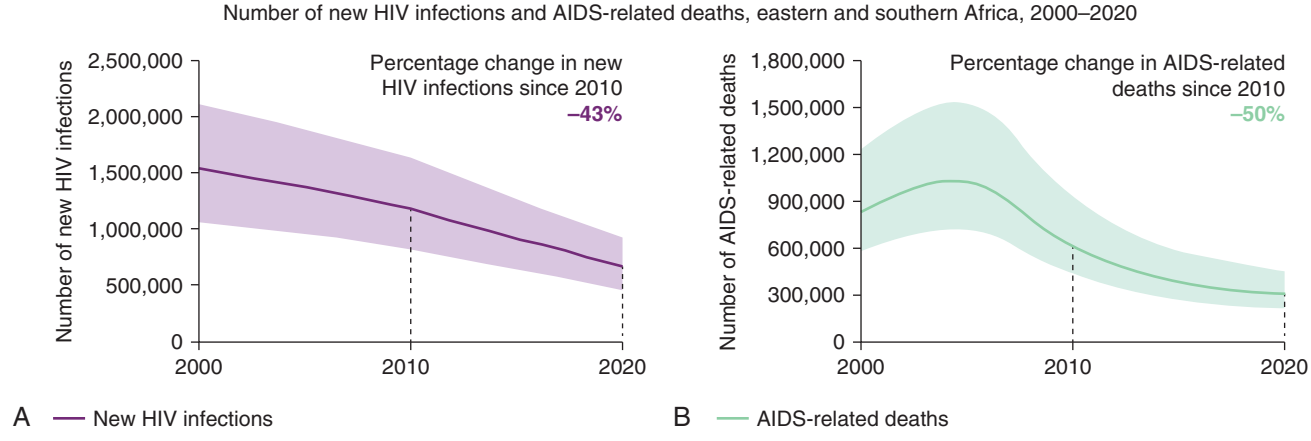
EASTERN AND SOUTHERN AFRICA

The 21 countries that make up eastern and southern Africa represent the epicenter of the global HIV/AIDS pandemic (see Table 353-1).[7] More than half of all people living with HIV reside in eastern and southern Africa. HIV prevalence varies widely across countries. The highest HIV prevalence rates in the world are found in Eswatini (27%). South Africa, the most populous country in this region, has an HIV prevalence of 19%. The main mode of transmission in this region is heterosexual sex. The number of new HIV infections in eastern and southern Africa has dropped from 1.1 million in 2010 to 670,000 in 2020, a 43% decline (E-Fig. 353-5). This decline has been even more pronounced in children with a 64% reduction from 2010 to 2020.

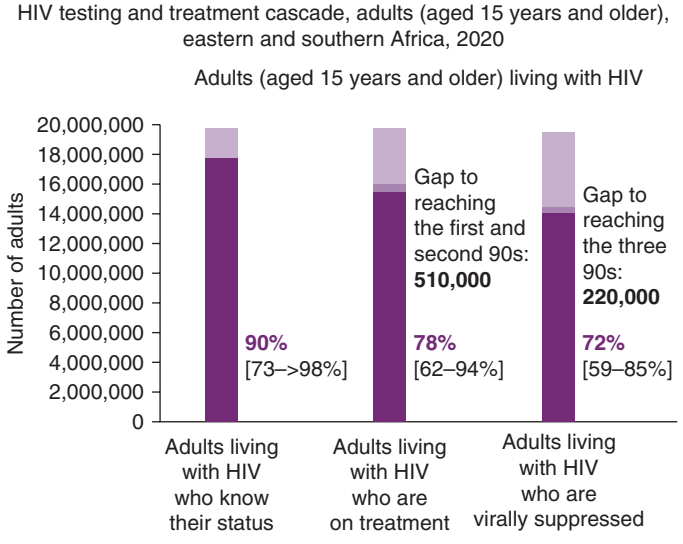
Knowledge of HIV status and HIV treatment coverage in eastern and southern Africa has risen steeply over the past decade. In 2020, about 90% of all people living with HIV in this region were aware of their HIV status (E-Fig. 353-6), 78% were on treatment, and an estimated 72% were virally suppressed. Significant progress has also been made with HIV treatment, with an estimated 16 million people on treatment in eastern and southern Africa in 2020, quadruple the number from 2010. As a result, mortality from AIDS-related deaths in this region has dropped by 50% since 2010 to a still substantial 310,000 deaths in 2020 (see E-Fig. 353-6). Continued support



E-FIGURE 353-4. Preexposure prophylaxis coverage (PrEP) by World Health Organization regions, 2020. (Data from UNAIDS. UNAIDS Data 2021. Geneva: UNAIDS; 2021.)



E-FIGURE 353-5. Trends in human immunodeficiency virus (HIV) infections (A) and deaths related to the acquired immunodeficiency syndrome (AIDS) (B), 2000-2020, eastern and southern Africa. (Data from UNAIDS. UNAIDS Data 2021. Geneva: UNAIDS; 2021.)



E-FIGURE 353-6. Human immunodeficiency virus (HIV) testing and treatment cascade, eastern and southern Africa in 2020. (Data from UNAIDS. UNAIDS Data 2021. Geneva: UNAIDS; 2021.)

of HIV treatment and prevention services will be needed if this region is to maintain and build on past advances.

WESTERN AND CENTRAL AFRICA

This region includes 25 countries and accounts for 12% of people living with HIV globally. Overall HIV prevalence is about 2.0% in this region, with prevalence ranging from 7.3% in Equatorial Guinea to 0.2% in Niger. The main mode of transmission is heterosexual sex. The number of new HIV infections in this region declined substantially between 2010 and 2020 from 400,000 to 200,000 (E-Fig. 353-7). Of note, Nigeria accounted for 43% of new HIV infections in this region in 2020 because of its large population, but the number of new infections decreased in Nigeria by 22% from 2010 to 2020.

Despite meaningful recent progress, knowledge of HIV serostatus remains suboptimal in this region, with 81% of people living with HIV being aware of their status, 77% being on treatment, and an estimated 62% being virally suppressed (E-Fig. 353-8), below UNAIDS 2020 goals of 73% viral suppression. AIDS-related mortality remains significant in this region, with 150,000 deaths in 2020 (see E-Fig. 353-7). HIV testing, prevention, and treatment programs must be continued in this region to address the ongoing epidemic.

NORTH AFRICA AND THE MIDDLE EAST

This region includes 20 countries and contains 230,000 people living with HIV. HIV prevalence averages less than 0.1% in countries in this region. The number of new HIV cases in North Africa and the Middle East has risen by 7% between 2010 and 2020 to around 16,000 cases annually (E-Fig. 353-9). The epidemic in this region is driven primarily by a combination of injection drug use and heterosexual transmission. Key populations and their partners contributed to almost all (95%) new infections in 2020. Three countries—Iran, Egypt, and Somalia—accounted for 60% of all new HIV infections in this region.

Despite some recent progress, knowledge of HIV status in this region in 2020 was only 61% (E-Fig. 353-10). Access to antiretroviral medications among all people living with HIV was 43%, which is very far off global goals. Viral suppression among all people living with HIV was only 37%, dramatically short of the UNAIDS 2020 goal of 73% viral suppression. In contrast to most other regions, AIDS-related deaths in North Africa and the Middle East have only decreased modestly, 17%, from 2010 to 2020 (see E-Fig. 353-9). This region needs substantial additional efforts to close major gaps in treatment and prevention cascades.

ASIA AND THE PACIFIC

After sub-Saharan Africa, Asia and the Pacific, which are home to 38 countries and 60% of the world's population, have the second largest number of HIV-positive individuals in the world, estimated at 5.8 million, which is 15% of the global total.[8] With the exception of Thailand, where HIV prevalence is 1.0%, national HIV prevalence levels remain comparatively low, well less than 1%, in most countries of Asia and the Pacific. However, low prevalences in large population bases can result in substantial HIV burdens. For example, an estimated adult HIV prevalence rate of 0.2% in India translates to 2.1 million people living with HIV—one of the highest total numbers in the world after South Africa. In 2020, there were 240,000 new infections in this region, a decline of 21% from 2010 (E-Fig. 353-11). Key populations and their partners contributed to almost all (94%) new infections in 2020.

Knowledge of HIV serostatus in Asia and the Pacific has increased steadily and in 2020 was at 76% (E-Fig. 353-12). Between countries there was significant variability, with awareness particularly high in countries such as Thailand (94%) compared with countries such as Indonesia (66%). About 3.7 million people living with HIV in this region were on antiretroviral therapy, representing 64% of this population, a remarkable increase from just 19% coverage in 2010 but still short of UNAIDS 90-90-90 goals for 2020. Viral suppression rates are estimated at 61% of all people living with HIV, a substantial gap from the 2020 73% target. With increased access to treatment, mortality has declined to 130,000 deaths in 2020, a 56% decrease from 2010 (see E-Fig. 353-11). Although progress has been made in this region, additional efforts are needed to reach key populations, address disparities in service and treatment access, and reach goals.[9]

EASTERN EUROPE AND CENTRAL ASIA

The 16 countries that make up this region contain 1.6 million people living with HIV. HIV prevalence averages about 1%, but, in contrast to other regions, the HIV epidemic in many countries of eastern Europe and central Asia is growing. An estimated 140,000 new cases of HIV occurred in 2020, a worrying 43% increase from 2010 (E-Fig. 353-13). The HIV epidemic in this region is strongly driven by people who inject drugs, who accounted for 43% of all new infections in 2020. The increase is dominated by the Russian Federation, which accounted for about 85% of all new HIV infections in this region in 2020. Ukraine accounted for another 7%. In this region, key populations and their partners contributed to almost all (91%) new infections in 2020.

Knowledge of HIV status in this region has improved slowly, with 70% aware in 2020 (E-Fig. 353-14). Access to antiretroviral therapy has improved from 2010, when only 12% of all people living with HIV were on treatment, to 53% now accessing antiretrovirals. However, the coverage rates remain well short of global goals. Among those on treatment, viral suppression is good; but, because of the low treatment access rates, only 50% of all people living with HIV in this region are virally suppressed. People who inject drugs, and who represent the population most at risk for HIV in eastern Europe and central Asia, are often least likely to receive treatment when they are medically eligible. Not surprisingly, AIDS-related deaths in this region have continued to rise. In 2020, there were 35,000 AIDS-related deaths, a 32% increase from 2010 (see E-Fig. 353-13). If more resources are not brought to bear and effective interventions are not implemented in the more severely affected countries in this region, it is likely that the epidemic in these countries will continue to worsen over the next decade.

LATIN AMERICA

An estimated 2.1 million adults and children are living with HIV in the 17 countries that make up the Latin American region. Overall HIV prevalence is 0.5% in this region. Brazil, with its large overall population, accounts for 930,000 people living with HIV. In 2020, the number of new HIV infections was 100,000, an unappreciable change from 2010 and in contrast to most other regions of the world, which have experienced declines (E-Fig. 353-15). Because of its size, Brazil accounted for about half of all new HIV infections in this region. HIV transmission in Latin America is predominantly through heterosexual or homosexual transmission. In this region, key populations and their partners contributed to almost all (92%) new infections in 2020.

Latin America has done modestly well with increasing HIV testing service access, with 81% of people living with HIV aware of their HIV status (E-Fig. 353-16). In 2020, there were 1.4 million people living with HIV on antiretroviral treatment in this region, nearly double the number from 2010; however, this figure represented only 65% of all people living with HIV. Viral suppression was estimated at 60% of all people living with HIV in 2020, still well short of 90-90-90 goals. Mortality from AIDS has modestly decreased in Latin America (see E-Fig. 353-15). From 2010 to 2020, there was a decrease of 21% to 31,000 annual deaths. Increased resources, wider access to antiretroviral therapy, and other strategies will be needed to move this region toward UNAIDS epidemic control goals.

CARIBBEAN

The 16 countries in the Caribbean region accounted for 330,000 people living with HIV in 2020. Overall HIV prevalence was about 1%. In several Caribbean countries, adult HIV prevalence rates are surpassed only by the rates experienced in sub-Saharan Africa, which makes this region the second most affected in the world. Haiti remains the worst affected, with an estimated national prevalence of 1.9%. The number of new cases in 2020 was 13,000, a 28% reduction since 2010 (E-Fig. 353-17). Homosexual and heterosexual transmission continues to be the major mode of transmission throughout the region. Key populations and their partners contributed to the majority (68%) of new infections in 2020.

Knowledge of HIV status in this region stands at 83%. Of all people living with HIV, only 67% are on antiretroviral treatment, and 60% are virologically suppressed, which remains well short of UNAIDS 2020 goals (E-Fig. 353-18). With increasing access to treatment, AIDS-related deaths have declined. In 2020, 6000 AIDS-related deaths were estimated to have occurred, a 51% decrease from 2010 (see E-Fig. 353-17). Resources for HIV treatment and prevention in this region remain limited, and additional measures and support will be needed to reach the 90-90-90 goals.

WESTERN AND CENTRAL EUROPE AND NORTH AMERICA

Thirty-nine countries make up this high-income region spread across two continents, where 2.2 million people living with HIV reside. Overall HIV prevalence is 0.3%, with no country having a prevalence higher than 0.8%. The number of new HIV infections has declined modestly (11%) from 2010 to 2020, with an estimated 67,000 new infections in 2020 (E-Fig. 353-19). The United States (see later) accounted for about half of all these new infections.

Certain countries, such as Denmark, the Netherlands, and Portugal, have experienced declines in new HIV infections of over 20% over the same time period. However, multiple countries, including Serbia, Slovakia, Czechia, and many others, have increasing new HIV infections. In this region, key populations and their partners contributed to almost all (96%) of new infections in 2020.

The HIV epidemic in western Europe is a result of a multitude of epidemics that differ in their timing, scale, and effects on populations. Unprotected sex between men remains the most important factor for spread in North America and most countries in western Europe. A large proportion of new HIV diagnoses in this region also occur through heterosexual intercourse. Injection drug use remains a major mode of transmission, particularly in the Baltic countries (Estonia, Latvia, and Lithuania). Most data from high-income countries demonstrate that the epidemic has shifted to the poor and marginalized sections of society. Recent introduction of preexposure prophylaxis (Chapter 356) has likely resulted in decreasing HIV transmission among men who have sex with men, at least in some settings.

In 2020, this well-resourced region had 90% of people living with HIV aware of their HIV serostatus (E-Fig. 353-20). In 2020, 83% of all people living with HIV were on treatment. Of all people living with HIV, an estimated 75% were virally suppressed, which met the 73% UNAIDS 2020 targets for viral suppression. As a result of expanded testing and treatment, AIDS-related deaths have decreased by about 30% from 2010 to 2020 with a current rate of 13,000 annual deaths (see E-Fig. 353-19). Despite significant successes, marginalized populations continue to share disproportionately in the burden of new infections and mortality. Continued efforts and new strategies will be needed to reach even more ambitious 2030 UNAIDS 95-95-95 targets as a region.[10]

THE UNITED STATES

By the end of 2019, an estimated 1.2 million people were living with HIV in the United States.[11] Nationally, the adult HIV prevalence was estimated to be about 0.5%. This increase in people living with HIV reflects mixed results in the United States' efforts to combat its epidemic. More people infected with HIV are living longer because of antiretroviral therapy; but, unfortunately, major gains in prevention have not been realized. Of people living with HIV, about 13% were not yet diagnosed and aware that they were infected with HIV in 2019. Of the 1.06 million who had been diagnosed, about 75% were men. Of these men, about 35% were Black, 32% were White, and 26% were Hispanic/Latino. Of the women, 57% were Black, 16% were White, and 21% were Hispanic/Latino. Of the men, most (73%) acquired infection attributable to male to male sexual contact,[12] with 10% due to heterosexual contact and 9% due to injection drug use. In contrast, among women, 77% of prevalent infections were attributable to heterosexual contact and 20% to injection drug use. Of note are the tremendous regional and state-by-state differences in the prevalence of HIV (see Fig. 353-3). The highest rates of adults and adolescents living with diagnosed HIV infection are found in southern states, the mid-Atlantic, and California.

The number of newly recorded HIV cases in the United States has varied only slightly since the late 1990s, although there has been a recent modest downward trend. In 2019, there were an estimated 34,800 new HIV infections, about an 8% decrease from 2015. About 70% of these new infections in 2019 occurred due to male to male sexual contact; 23% were attributed to heterosexual contact; and 7% were due to injection drug use. Since 2015, there has been no major change in the share of new HIV infections attributed to heterosexuals (23%). In contrast there was a 9% increase among people who inject drugs. Men accounted for 79% of all new diagnoses. Blacks accounted for 42% of all new HIV diagnoses; Hispanics/Latino accounted for 29%. Accordingly, two of the most-affected subpopulations are Black gay and bisexual men, who accounted for 26% of all new HIV infections in 2019, and Latino gay and bisexual men, who accounted for another 23%. Regarding age, in 2019, the highest rates of new HIV infections were in persons ages 25 to 29 years (31 diagnoses per 100,000 population) followed by those 20 to 24 years (27.3). Similar to HIV prevalence rates, there was also large geographic variations in new HIV diagnosis rates, with the highest rates found in the South (e.g., Georgia, Florida), the mid-Atlantic (e.g., Maryland, New York), California, Texas, and Nevada.

In the United States, more than 760,000 people with AIDS have died since the epidemic began. Mortality peaked in 1995 and has steadily declined since then with the use of increasingly effective antiretroviral therapy, although the slope of decline has been modest or flat for more than a decade now (Fig. 353-4). In 2019, there were about 15,800 deaths from any cause of persons with diagnosed HIV infection, a rate of 5.7 per 100,000. Marked racial/ethnic disparities were evident, with death rates among Black Americans (16.1/100,000) much higher compared with Hispanic/Latinos (4.5/100,000) and Whites (2.5/100,000). Black Americans accounted for about 42% of all deaths of persons with diagnosed HIV infection, Hispanic/Latinos 17%, and Whites 31%. Death rates were higher in men (8.9/100,000) compared with women (2.6/100,000), and higher in the Northeast and South compared with the Midwest and West.

An estimated 13% of people living with HIV in the United States are unaware of their HIV status. Moreover, in 2019, 34% of people living with HIV have not accessed HIV care, and only 57% of all people living with HIV were virally suppressed in the United States (Fig. 353-5). Viral suppression was particularly low in persons ages 13 to 24 years compared with persons older than 45 years. Black Americans also had the lowest rates of viral suppression compared with other races. New resources and strategies will be needed to close these disparities and gaps in the United States' HIV care continuum.[13]

With such a long-standing epidemic, complacency has increased, and some prevention efforts have dwindled as a result of declining morbidity and mortality. The increasing rate of effective viral suppression to reduce infectivity[A4] as well as the uptake of preexposure prophylaxis by mostly men who have sex with men offers hope but is tempered by increasing rates of sexually transmitted

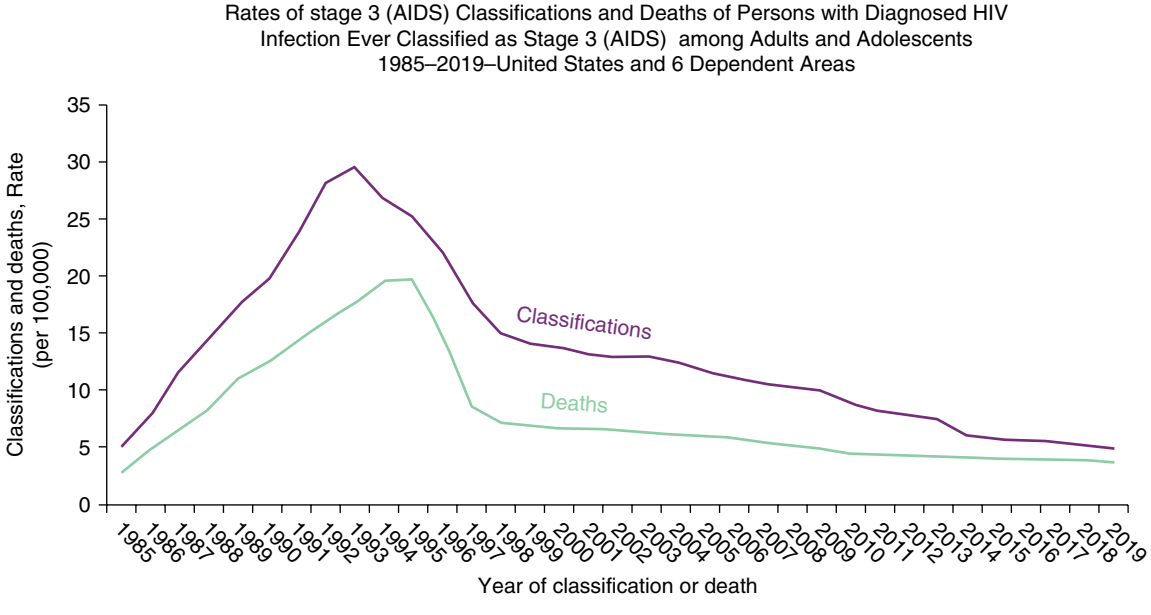

FIGURE 353-4. Trends in AIDS classifications and deaths among adults and adolescents in the United States and dependent areas, 1985-2019. FIGURE 354-1. The HIV virion. The HIV virion contains viral gene products and cellular components essential to transmit infection and establish the proviral state. HIV virions are roughly spherical particles with a diameter of 80 to 120 nm and are composed of a viral core enveloped by a lipid membrane. The core of the mature virion is a conelike structure, composed of the HIV p24 capsid (CA), which encapsidates components necessary for replication: two copies of HIV genomic RNA template complexed with HIV p6 nucleocapsid (NC); tRNA^{lys} primer; HIV enzymes reverse transcriptase, protease, and integrase; and HIV Vif. The viral envelope, which is derived from the plasma membrane of the host cell as HIV undergoes budding, contains viral proteins Gp120 (SU) and Gp41 (TM), as well as a structural matrix protein, MA. HIV = human immunodeficiency virus; tRNA = transfer RNA.

infections and uneven access to preexposure prophylaxis for other high-risk groups.[14] The United States' Ending the HIV Epidemic goals are, by 2025, to decrease the number of new HIV diagnoses to about 9500 cases annually, to increase the percentage of people aware of their HIV diagnosis to 95%, and increase viral suppression to 95%. Renewed and novel efforts to enhance treatment and prevention will be needed to achieve these ambitious targets and drive down rates of new HIV infections and HIV-associated morbidity and mortality in the United States.[15]

354 PATHOBIOLOGY OF HUMAN IMMUNODEFICIENCY VIRUSES

JOEL N. BLANKSON, ROBERT F. SILICIANO, AND FRANK MALDARELLI

Human immunodeficiency viruses (HIV-1, HIV-2) cause progressive immune deficiency and death from opportunistic infections or neoplastic diseases. Increased understanding of HIV pathobiology has led to significant advances in diagnosis (Chapter 355), prevention (Chapter 356), and treatment (Chapter 357) that have reduced morbidity and mortality, and tipped the balance toward control of the epidemic worldwide.

The Pathogen

HIV is a member of the lentivirus genus of the Orthoretrovirinae subfamily of the Retroviridae family of Revtraviricetes. All retroviruses contain reverse transcriptase, which catalyzes the synthesis of DNA from an RNA template. Retroviruses are widely distributed among vertebrates; lentiviruses cause chronic, recurrent, or progressive diseases, including immunodeficiencies, in various mammalian species. Several cross-species transmissions of lentiviruses from primates to humans were the source of human immunodeficiency viruses (Chapter 353).

HIV virions are enveloped particles that are approximately 100 nm in diameter (Fig. 354-1) and contain: two single-stranded (+) sense RNA copies, which code for HIV genes (E-Fig. 354-1); the tRNA primer, within a virion protein core composed of structural proteins; the viral enzymes; reverse transcriptase and integrase essential for replication; and viral factors (Vpr and Vif) that are necessary to evade intracellular restriction. The viral envelope, which is derived from the host plasma membrane at budding, contains viral proteins Gp120 (SU) and Gp41 (TM), as well as a structural matrix protein, MA.

REPLICATION CYCLE

Viral replication (E-Fig. 354-2) is initiated by direct contact of virions or infected cells with susceptible host cells (E-Fig. 354-2A)[1] mediated by surface Env glycoprotein trimers of HIV sp120 SU noncovalently bound to HIV gp41 TM. Attachment is mediated by SU, which engages two distinct cell surface proteins, a receptor, and a coreceptor. HIV initially binds the CD4 receptor, thereby resulting in conformational change in Env and facilitating binding to a coreceptor, typically either the human chemokine receptor CCR5[2] or CXCR4 (although CCR5/CXCR4 dual-tropic viruses circulate as well). Engaging both receptor and coreceptor results in conformational change in TM to drive membrane fusion. Inhibitors of SU-CD4, SU-CCR5 interactions, and TM-mediated fusion are effective treatments for HIV.

354 PATHOBIOLOGY OF HUMAN IMMUNODEFICIENCY VIRUSES

JOEL N. BLANKSON, ROBERT F. SILICIANO, AND FRANK MALDARELLI

Human immunodeficiency viruses (HIV-1, HIV-2) cause progressive immune deficiency and death from opportunistic infections or neoplastic diseases. Increased understanding of HIV pathobiology has led to significant advances in diagnosis (Chapter 355), prevention (Chapter 356), and treatment (Chapter 357) that have reduced morbidity and mortality, and tipped the balance toward control of the epidemic worldwide.

The Pathogen

HIV is a member of the lentivirus genus of the Orthoretrovirinae subfamily of the Retroviridae family of Revtraviricetes. All retroviruses contain reverse transcriptase, which catalyzes the synthesis of DNA from an RNA template. Retroviruses are widely distributed among vertebrates; lentiviruses cause chronic, recurrent, or progressive diseases, including immunodeficiencies, in various mammalian species. Several cross-species transmissions of lentiviruses from primates to humans were the source of human immunodeficiency viruses (Chapter 353).

HIV virions are enveloped particles that are approximately 100 nm in diameter (Fig. 354-1) and contain: two single-stranded (+) sense RNA copies, which code for HIV genes (E-Fig. 354-1); the tRNA primer, within a virion protein core composed of structural proteins; the viral enzymes; reverse transcriptase and integrase essential for replication; and viral factors (Vpr and Vif) that are necessary to evade intracellular restriction. The viral envelope, which is derived from the host plasma membrane at budding, contains viral proteins Gp120 (SU) and Gp41 (TM), as well as a structural matrix protein, MA.

REPLICATION CYCLE

Viral replication (E-Fig. 354-2) is initiated by direct contact of virions or infected cells with susceptible host cells (E-Fig. 354-2A)[1] mediated by surface Env glycoprotein trimers of HIV sp120 SU noncovalently bound to HIV gp41 TM. Attachment is mediated by SU, which engages two distinct cell surface proteins, a receptor, and a coreceptor. HIV initially binds the CD4 receptor, thereby resulting in conformational change in Env and facilitating binding to a coreceptor, typically either the human chemokine receptor CCR5[2] or CXCR4 (although CCR5/CXCR4 dual-tropic viruses circulate as well). Engaging both receptor and coreceptor results in conformational change in TM to drive membrane fusion. Inhibitors of SU-CD4, SU-CCR5 interactions, and TM-mediated fusion are effective treatments for HIV.

ABSTRACT

Human immunodeficiency viruses (HIV), which are enveloped, (+)stranded RNA virus members of the retrovirus family, have infected over 37 million individuals worldwide. HIV establishes a chronic infection in anatomic compartments throughout the body. Untreated infection results in progressive lymphopenia and immunodeficiency, ultimately resulting in death from opportunistic infections or neoplasms. Replication takes place in lymphoid and myeloid cells that express the viral receptor (CD4) and a coreceptor (CCR5 or CXCR4). Replication proceeds by reverse transcription of viral RNA into HIV DNA, which is integrated into the host genome. Gene expression is controlled by viral regulatory genes and executed by host machinery; gene products traffic to the cell surface where virions assemble and bud from the cell membrane. The majority of infected cells are rapidly eliminated, but a small minority persist for prolonged periods and undergo clonal expansion, thereby maintaining a lifelong reservoir. Serologic and cellular immune responses are initiated shortly after transmission but are ineffective in most individuals, thereby resulting in the inexorable loss of CD4 cells, immune exhaustion, and impaired immune responses. In a small minority of patients known as elite controllers, HIV infection may be naturally suppressed, although persistent immune activation contributes to comorbid conditions. HIV infection is controlled but not cured through the use of combination antiretroviral therapy, which blocks active replication cycles. Ongoing immune activation persists, however, and contributes to morbidity and mortality. Studies to eradicate or control HIV without antiretroviral therapy are under active investigation.

E-FIGURE 354-1. **Major HIV genes. A**, HIV proviral DNA with complete long terminal repeat (LTR). HIV encodes nine genes whose products are required for structural, enzymatic, regulatory, and innate immune neutralization functions. By convention, HIV genes (color coded, not to scale) are denoted in lower italics (*gag, pol*, etc.) with names that broadly reflect their function, location in the virion, or a historical vestige of prior viral classification (e.g., *gag*, "group antigen"). Additional genes that function in regulation or replication (*tat, rev, vpr*) or in blocking immune responses to HIV (*vif, vpu, nef*); all are critical for HIV infection in vivo. **B**, Function of HIV viral gene products. Host components interacting with each gene product are noted, and gene products are indicated for which U.S. Food and Drug Administration–approved therapeutic drugs are available. *Down-regulated by 1β HIV binding partner. DNA = deoxyribonucleic acid; FDA = U.S. Food and Drug Administration; HIV = human immunodeficiency virus; RNA = ribonucleic acid; TAR = transactivation response.

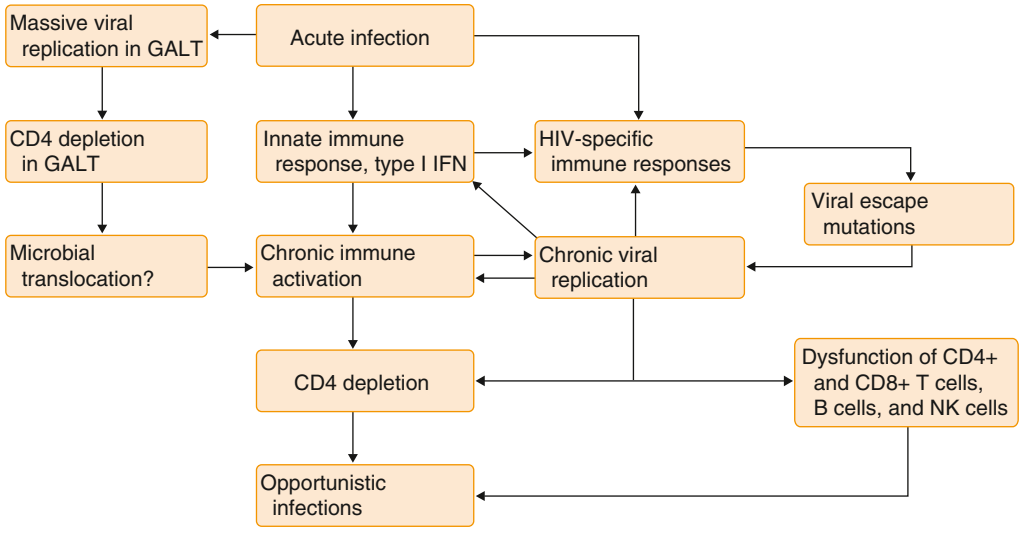

FIGURE 354-2. Parameters involved in chronic immune activation and CD4⁺ T-cell depletion. GALT = gut-associated lymphoid tissue; HIV = human immunodeficiency virus; IFN = interferon; NK = natural killer.

A key event in HIV replication is the conversion of virion RNA into double-stranded DNA by reverse transcriptase. Effective reverse transcription and uncoating occurs in the nucleus, followed directly by integration into the host's genome[3] (E-Fig 354-2B and 2C); potent inhibitors of reverse transcriptase, integrase, and uncoating are now FDA-approved (Chapter 357).

Reverse transcriptase is a highly error-prone enzyme, with only a rudimentary editing function; approximately one mutation per virion occurs per replication cycle. The HIV generation time is estimated to be relatively short (1 to 2 days), and the replicating population size is substantial. This combination of rapid and error-prone replication results in a genetically diverse population that can respond rapidly to immune- or drug-selective pressure. Thus rapid error-prone replication represents a critical pathogenic determinant for HIV. Estimates indicate that variants with single resistance mutations to individual antiretroviral agents preexist in HIV-infected patients *prior to* initiating antiretroviral therapy. As a consequence, antiretroviral therapy requires combinations of drugs with distinct resistance profiles to prevent the emergence of resistance. Combinations that inhibit one to three steps in replication can be effective (Chapter 357).

After the proviral state is established, HIV produces viral RNA and proteins using viral factors in concert with cellular mechanisms of transcription and translation.[4] HIV replicates not by dismantling cell functions but rather by using specific interactions among host factors and specific viral gene products that drive high levels of HIV RNA transcription (Tat), facilitate balanced RNA transport (Rev), and help traffic of HIV proteins to membranes for virion budding (Gag) (E-Fig. 354-3). Following budding, HIV Gag precursor proteins require proteolytic processing by the viral enzyme protease for mature core formation, which is required for viral infectivity. Potent protease inhibitors, which block this step, are important components of combination antiretroviral therapy (Chapter 357). Maturation of HIV virions represents a new target for inhibition, and several agents are under active investigation.[5]

HIV infection triggers a number of intracellular innate responses, which, if left unchecked, would arrest HIV replication. Several interferon-induced genes inhibit HIV replication, including the ABOBEC family of nucleic acid editing enzymes; the cell surface protein BST-2 (tetherin), which blocks release of virions from the cell surface; and SERINC 3/5, which incorporates into virion membranes and reduces infectivity of the produced virions. In each case, a viral factor (Vif for APOBEC, Vpu for BST-2, and Nef for SERINC 3/5) blocks these innate mechanisms by binding and redirecting corresponding host proteins to ubiquitin-induced degradation. Several HIV proteins (Vpiu, Nef) also down-modulate immune cell surface proteins CD4 and MHC molecules, thereby hindering adaptive immune responses.[6]

PHYSIOLOGY OF HIV INFECTION

UNTREATED INFECTION

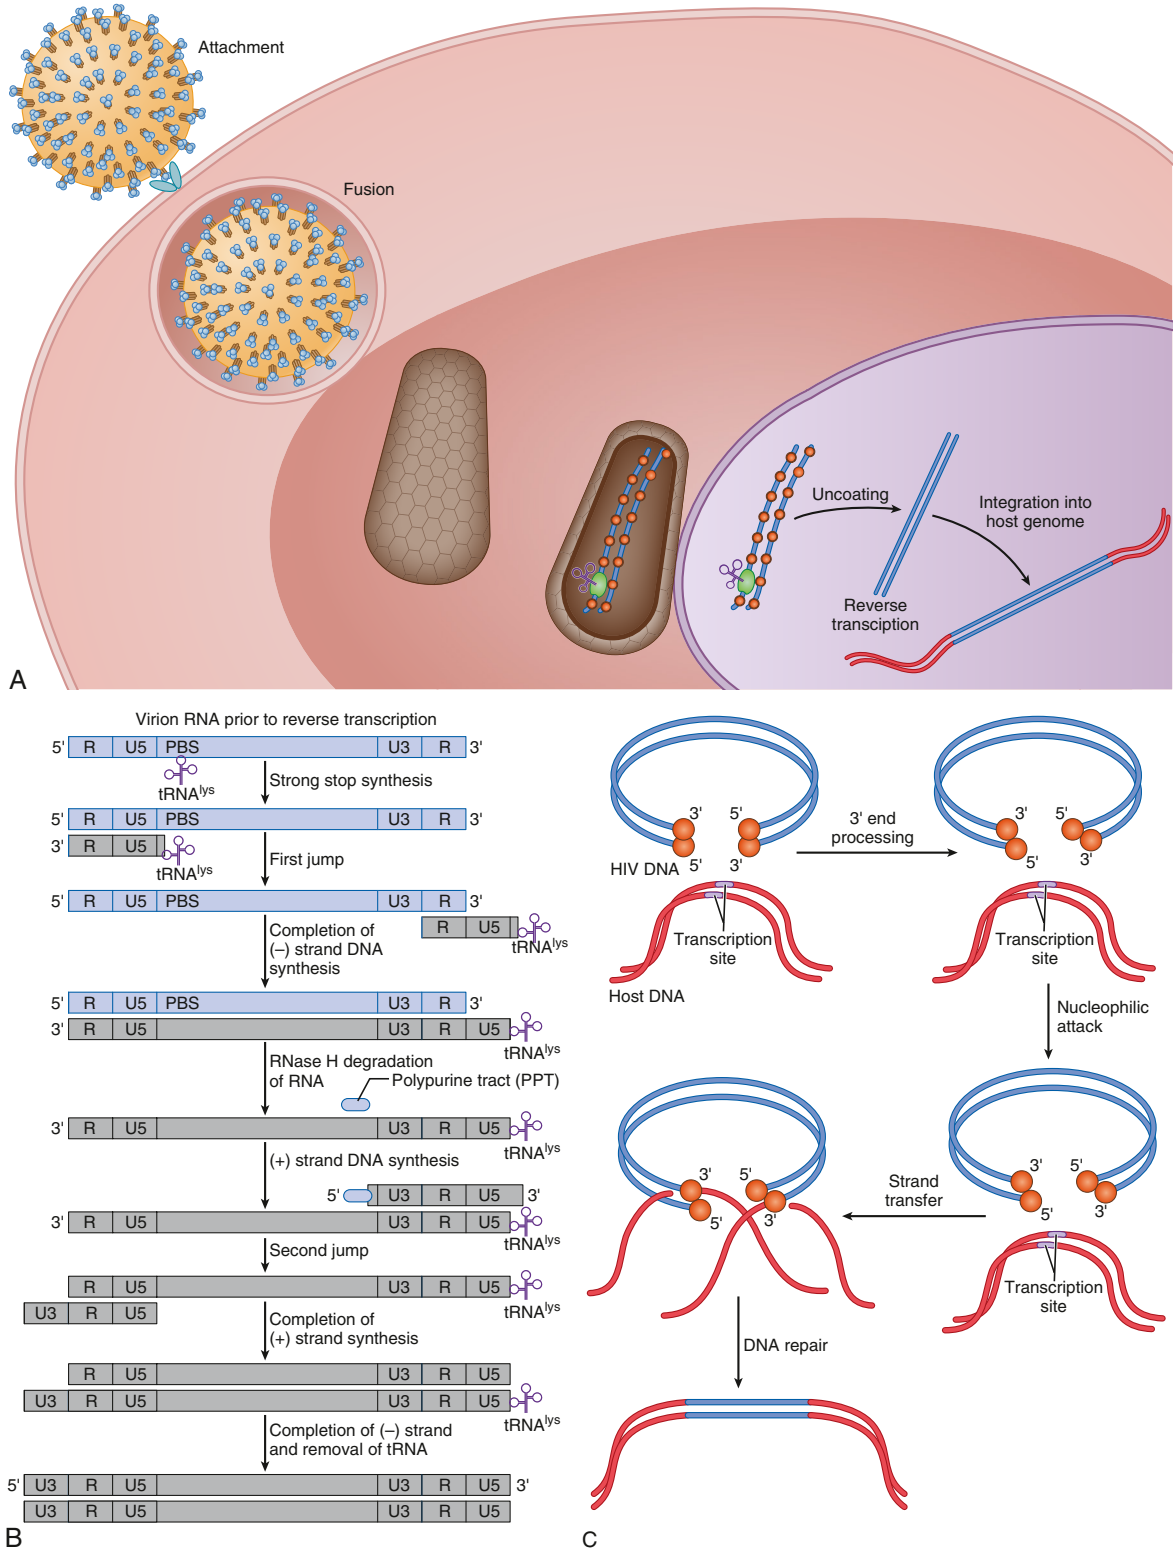
FATE OF INFECTED CELLS

By the completion of the infectious cycle, HIV has produced progeny for the next round of infection, obstructed adaptive and innate immune responses, and established a proviral state in the infected cell. Despite multiple mechanisms of immune evasion, the majority of infected cells (>99%) die within 1 to 2 days of infection. Thus the virus has a strikingly short period to engage critical cell pathways to complete replication while most cells are being destroyed. A minority of infected cells survive infection and persist for prolonged periods.

The host mounts a vigorous immune response after HIV-1 infection. The virus is thought to activate plasmacytoid dendritic cells through toll-like receptors, thereby resulting in the secretion of type I interferons and other inflammatory cytokines. Whereas type I interferons have direct antiviral properties and enhance the HIV-1–specific immune response, excessive secretion may play a key role in pathogenic immune activation of CD4+ and CD8+ T cells (Fig. 354-2). Natural killer (NK) cells, which are important effector cells in the innate immune response, become activated when infection of target cells by HIV-1 or other viruses results in the downregulation of HLA molecules. Patients expressing certain NK receptor alleles are more likely to become long-term nonprogressors, thereby suggesting that these cells may play a protective role possibly by controlling early HIV-1 replication by leading to the development of an effective adaptive immune response. Myeloid dendritic cells, which play a key role in the presentation of HIV-1 antigens to HIV-1–specific CD4+ and CD8+ T cells, initiate the adaptive immune response. Dendritic cells express CD4 molecules and bind HIV-1. In the process of presenting antigen, these cells may inadvertently transmit HIV-1 to clusters of activated CD4+ T cells.

The role of the humoral response in HIV-1 infection is not clear. HIV-1–specific antibodies, which are used to diagnose HIV-1 infection, do not develop until after peak viremia occurs. A subset of the antibodies that eventually appear are capable of preventing infection by blocking the interaction of the HIV-1 envelope protein gp120 with CD4 and with coreceptor proteins on the surface of target cells. These so-called neutralizing antibodies are present at relatively low titers and have limited access to the critical regions of gp120. Although neutralizing antibodies can exert significant selective pressure on the virus, immunologic escape is common, and the bulk of evidence suggests that these antibodies do not play a major role in the control of viral replication in most long-term nonprogressors.[7]

The selective depletion of CD4+ T cells, which play a major role in the adaptive immune response, is the main reason that HIV-1 infection results in such profound immunosuppression. The ability of HIV-1–specific CD4+ T cells to proliferate and to secrete key cytokines such as interleukin-2 is lost shortly after primary infection, thereby setting up the entire HIV-1–specific response for failure. CD8+ T cells contribute to the control of HIV-1 infection by the direct lysis of infected cells and by the secretion of soluble factors, such as macrophage inflammatory protein 1β, which bind to chemokine receptors, thereby preventing HIV-1 entry into target cells. However, the HIV-1–specific CD8+ T-cell response that partially controls HIV-1 replication after peak viremia in primary infection does not achieve sterilizing immunity, partly because of a reservoir of latent virus that develops in resting memory CD4+ T cells shortly after infection. These quiescent cells probably do not make HIV-1 proteins and thus are not recognized by cytolytic T-lymphocytes. Furthermore, the cytolytic T-lymphocyte response



E-FIGURE 354-2. Steps in viral replication. A, Early steps in replication. Viral replication is initiated by direct contact of virions or infected cells with susceptible host cells and is mediated by surface Env glycoprotein trimeric complexes, which consist of HIV sp120 SU noncovalently bound to HIV gp41 TM. The attachment phase is mediated exclusively by SU, which engages two distinct cell surface proteins for attachment: a receptor and a coreceptor. HIV initially binds CD4, thereby resulting in conformational change in Env, which facilitates coreceptor binding. Typically, SU proteins use either the human chemokine receptor 5 (CCR5) or the human chemokine receptor 4 (CXCR4) to infect CD4+ T cells, but CCR5/CXCR4 dual tropic viruses circulate as well. Inhibition of SU-CD4 and SU-coreceptor interactions has been achieved pharmacologically (Chapter 357). Attachment results in conformational changes in TM, which reorganizes into six alpha helix bundles that drive fusion reaction; peptides that bind these alpha helices have been developed as fusion inhibitors (Chapter 357). Once membrane fusion occurs, the core is released into the cytoplasm and travels to the nucleus. **B**, Reverse transcription. The (+)-strand template strands of HIV RNA are complexed with reverse transcriptase and a specific $tRNA^{lys}$ that functions as a primer located at a specific primer binding site (see E-Fig. 354-1) near the 5′ end of the template HIV RNA. Reverse transcription is a multistep process (see E-Fig. 354-3) that first synthesizes a DNA copy of the RNA genome and then excises the RNA from the RNA-DNA hybrid using an RNase H function of reverse transcriptase; RNA removal is incomplete, and residual RNA in a region denoted the polypurine tract then serves to prime the next round of DNA synthesis. During reverse transcription a number of strand transfer events permit opportunities for frequent recombination. Reverse transcription was the first target for antiretroviral therapy, and a number of direct and allosteric inhibitors of reverse transcription have been developed (Chapter 357). All reverse transcription inhibitors inhibit RNA-dependent DNA synthesis or DNA-dependent DNA synthesis. Nucleoside and nucleotide reverse transcriptase inhibitors, which are dideoxy analogues of deoxynucleotides that are incorporated as the template is copied and act as chain terminators that block additional nucleic acid synthesis. Non-nucleoside inhibitors of reverse transcription bind to reverse transcriptase in a hydrophobic domain proximal to the active site, thereby deforming the enzyme structure and disrupting nucleic acid synthesis. **C**, Newly synthesized HIV DNA transports to the nucleus for integration into the host genome. A complex of the HIV protein integrase, newly synthesized HIV DNA, and associated proteins has been labeled an *intasome*. Structural studies have revealed that a tetramer of integrase molecules is bound to the ends of the retroviral DNA and brings the DNA ends in close proximity, poised for integration into the genome in a multistep process. Integration is a highly successful target for antiretroviral therapy, and inhibitors that block the transfer of HIV DNA strand into the host genome are now first-line antiretroviral choices in clinical practice (see Chapter 357). E. Generating infectious virions

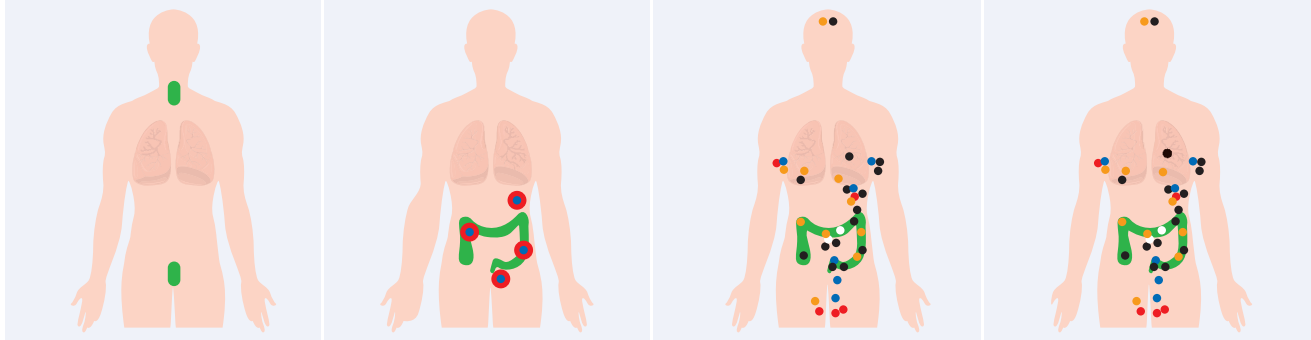
E-FIGURE 354-3. Generating infectious virions: transcription and post-transcription events. A, Transcription. The integrated provirus is expressed in the context of host chromatin. Retroviruses transcribe all of their genes from a single promoter. The U3 portion of the HIV long terminal repeat contains binding sites for transcription factors common in lymphocytes and macrophage-monocyte lineages, including activator protein 1 (AP-1), specificity protein 1 (SP-1), nuclear factor kappa B (NF-κB), and nuclear factor of activated T cells (NFAT) binding sites. The presence of the viral transcription factor transactivator of transcription (Tat) markedly stimulates transcription through binding to a specific RNA enhancer, which is denoted as the transactivating region (TAR), and recruiting additional transcription factors. **B,** Post-transcription. Full-length HIV RNA is processed for expression of all nine gene products and encapsidated as the viral genome into virions. To provide sufficient mRNA species to express all HIV proteins, RNA processing is highly regulated by alternative splicing and differential RNA transport. Full-length RNA consists of a primary capped mRNA of approximately 9.2 kb that undergoes alternative splicing to produce three broad classes of RNA species: 9.2-kb unspliced RNA, responsible for translation of *gag/pol;* a number of distinct 4.5-kb singly spliced RNA species, responsible for translation of *vif, vpr*, and *vpu/env;* and 1.8-kb multiply spliced species, responsible for *tat, rev*, and *nef*. **C,** Trafficking. Multiply spliced 1.8-kb RNAs are constitutively expressed, but unspliced and singly spliced HIV mRNAs require specific transport out of the nucleus. To export unspliced and singly spliced HIV RNAs, the viral protein Rev binds to a specific region in the *env* portion of the unspliced and singly spliced RNA, denoted as the Rev responsive element (RRE); the RRE is a sequence of c.240 nt that folds into a specific structure to which Rev binds. The Rev-RNA complex then engages the nuclear host CRM-1 transport apparatus, which transports RNA out of the nucleus. Engaging appropriate host elements therefore results in a balance of 9.2-, 4.5-, and 1.8-kb mRNA species. **D,** Budding. HIV virion proteins and virion RNA species traffic to the plasma membrane, where virion assembly takes place. Gag has self-assembly properties, but correct initial assembly of the virion core into a hexagonal lattice includes incorporation of virion RNA and additional factors. Virion RNA undergoes dimerization largely through direct RNA-RNA interactions that require specialized RNA sequences, denoted psi sequences, at the 5′ region of the genome favoring incorporation of only unspliced HIV RNA species. Gag accumulates in specialized membrane microdomains enriched with sphingomyelin-saturated phospholipids and cholesterol typical of lipid rafts and binds components of the endosomal sorting complexes required for transport (ESCRT) pathway. By recruiting ESCRT to sites of HIV assembly on the plasma membrane, HIV engages a highly specialized pathway to execute budding. During processing, the core lattice begins to bend by introducing pentamers of CA at critical points of the hexagonal lattice, thereby effectively folding the structure into a fullerene-like cone that encapsidates dimeric HIV RNA-$tRNA^{lys}$ and HIV enzymes. **E,** Generating infectious virions. Nascent virions require proteolytic processing of the Gag and GagPol precursor proteins by HIV protease to become infectious. Protease is embedded as part of the GagPol precursor, cleaves itself from the precursor, and then proceeds to process Gag and GagPol into component proteins. Processing is essential for virion infectivity, and protease inhibitors are highly effective agents in HIV therapy (Chapter 357). ESCRT = endosomal sorting complex required for transport; GPI = glycosylphosphatidylinositol; HIV = human immunodeficiency virus; tRNA = transfer ribonucleic acid.

	Transmission	Acute Retroviral Syndrome	Chronic Infection	Late Stage Disease/AIDS
				


Clinical	HIV exposure Mucous membranes Injection into blood or skin	Fever Rash Fatigue Diarrhea Headache	Lymphadenopathy Mild cognitive defects	Opportunistic infections Neoplastic diseases Dementia
Anatomic	Local spread at transmission site Rectum Genital Oropharynx	Extensive spread in GALT Destruction of gut barrier function antigen-antibody deposition in skin	Established reservoirs in lymphoid and non lymphoid tissue Elevated immune activation	Profound immune deficiency Depleted hyalinized lymph nodes Loss of Immune surveillance for neoplasms Elevated immune activation
Immune	Absent	Low avidity antibody antigen-antibody deposition in skin	Antibody (including neutralizing); interferon, cytokine response CD and CTL, NK, Brode immune activation Progressive CD4 lymphopenia T cell exhaustion	Robust antibody response CD4 responses depleted
Viral	Limited genetic variants transmitted	Ongoing cycles of HIV replication Limited genetic diversity includes CTL escape mutations CCR5 coreceptor utilizing env Interferon-resistant variants High viral load in blood Small reservoir of long-lived cells	Ongoing cycles of HIV replication High genetic diversity CCR5 coreceptor ulilizing env Interferon-sensitive variants Set point viral load in blood Clonal expansion of presistently infected long-lived cells	Ongoing cycles of HIV replication High genetic diversity CCR5 and CXCR4 coreceptor utilizing env Interferon-sensitive variants Rising viral load in blood Clonal expansion of persistently infected long lived cells

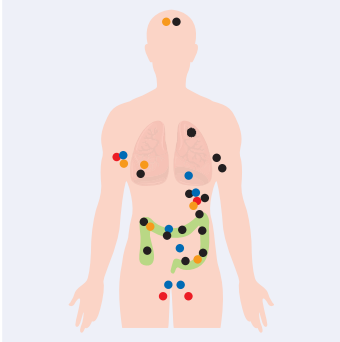
in patients with progressive disease is of poor quality with limited proliferative capacity. Most important, the low fidelity of HIV-1 reverse transcriptase results in the development of mutations with each round of replication. Mutations that lead to escape from cytolytic T-lymphocyte responses have an advantage and are thus rapidly predominate.

THE EFFECT OF HIV-1 REPLICATION ON THE IMMUNE SYSTEM

Although the HIV-1–specific immune response helps limit the rate of viral replication, sterilizing immunity is never achieved and the virus has a negative impact on the immune system. Continuous viral replication results in chronic immune activation (see Fig. 354-3), but the precise mechanism is not understood. The chronic immune response to the virus may lead to nonspecific inflammation, and microbial translocation resulting from the depletion of CD4+ T cells in the gut-associated lymphoid tissue may also be important. Whatever the mechanism, immune activation appears to drive the depletion of CD4+ T cells. In untreated patients, the level of immune activation markers on CD4+ and CD8+ T cells correlates better with the rate of CD4 decline than does the magnitude of the viral load. Increased levels of activation markers are seen on NK cells, B cells, CD4+ T cells, and CD8+ T cells.[8] Activation is accompanied by an increase in the turnover rate of these cells. The compromised function of NK cells may predispose to the poor control of other viruses. B-cell defects result in hypergammaglobulinemia and the production of autoantibodies. Poor antibody responses to vaccines are also seen as CD4+ T cells decline.

The loss of infected CD4+ T cells contributes to a depletion in CD4+ T cells even though only 1% or less of these cells are infected at any given time during chronic infection. Thus, it is currently thought that chronic immune activation leading to the death of noninfected CD4+ T cells is the principal mechanism for CD4 depletion. In addition to the quantitative loss of CD4+ T cells in HIV-1 infection, marked skewing of the CD4 T-cell repertoire is seen, and there is a diminished qualitative memory response to recall antigens long before the CD4+ T-cell count drops to 200 cells/μL. The chronic activation and high turnover rate of these cells eventually result in the progressive CD4 decline that is characteristic of HIV-1 infection.



Clinical	Largely asymptomatic Elevated cardiovascular disease Complications of immune activation
Anatomic	Limited restoration of lymphoid architecture; incomplete restoration of gut barrier function Cognitive improvement
Immune	Reduced antibody response Reduced but persistent immune activation Reduced but persistent T cell exhaustion
Viral	Low level viremia (1–2 copies HIV RNA/ml plasma) Absence of viral replication cycles No molecular evolution Persistence of infected cells in resting memory subsets Clonal expansion of long-lived cells

FIGURE 354-4. Characteristics of HIV-infected individuals undergoing antiretroviral therapy. HIV = human immunodeficiency virus.

There is evidence of immune exhaustion for both CD4+ and CD8+ T cells, and there is decline in the qualitative features of the CD8+ T-cell response to other chronic viruses such as cytomegalovirus (Chapter 347) and Epstein-Barr virus (Chapter 348). This decline may be the result of anergy or depletion of the CD4+ T cells that are needed to sustain functional CD8+ T-cell responses.

CLINICAL CONSEQUENCES OF HIV INFECTION
